Motor/Coordination/Extrapyramidal: increased tremor, chorea, loss of balance, restlessness, blepharospasm, increased bradykinesia, facial grimace, falling down, heavy leg, muscle twitch*, myoclonic jerks*, stiff neck, tardive dyskinesia, dystonic symptoms, dyskinesia, involuntary movements, freezing, festination, increased apraxia, muscle cramps.

Mental Status/Behavioral/Psychiatric: hallucinations, dizziness, confusion, anxiety, depression, drowsiness, behavior/mood change, dreams/nightmares, tiredness, delusions, disorientation, lightheadedness, impaired memory*, increased energy*, transient high*, hollow feeling, lethargy/malaise, apathy, overstimulation, vertigo, personality change, sleep disturbance, restlessness, weakness, transient irritability.

Pain/Altered Sensation: headache, back pain, leg pain, tinnitus, migraine, supraorbital pain, throat burning, generalized ache, chills, numbness of toes/fingers, taste disturbance.

AUTONOMIC NERVOUS SYSTEM: Dry mouth, blurred vision, sexual dysfunction.

CARDIOVASCULAR: Orthostatic hypotension, hypertension, arrhythmia, palpitations, new or increased angina pectoris, hypotension, tachycardia, peripheral edema, sinus bradycardia, syncope.

GASTROINTESTINAL: Nausea/vomiting, constipation, weight loss, anorexia, poor appetite, dysphagia, diarrhea, heartburn, rectal bleeding, bruxism*, gastrointestinal bleeding (exacerbation of preexisting ulcer disease).

GENITOURINARY/GYNECOLOGIC/ENDOCRINE: Slow urination, transient anorgasmia*, nocturia, prostatic hypertrophy, urinary hesitancy, urinary retention, decreased penile sensation*, urinary frequency.

SKIN AND APPENDAGES: Increased sweating, diaphoresis, facial hair, hair loss, hematoma, rash, photosensitivity.

MISCELLANEOUS: Asthma, diplopia, shortness of breath, speech affected.

POSTMARKETING REPORTS: The following experiences were described in spontaneous postmarketing reports. These reports do not provide sufficient information to establish a clear causal relationship with the use of ELDEPRYL® (SELEGILINE HYDROCHLORIDE).

CNS: Seizure in dialyzed chronic renal failure patient on concomitant medications.

*indicates events reported only at doses greater than 10 mg/day.

Incidence of Treatment-Emergent Adverse Experiences in the Placebo-Controlled Clinical Trial

Adverse Event	Number of Patients Reporting Events	
	selegiline hydrochloride N = 49	placebo N = 50
Nausea	10	3
Dizziness/Lightheaded/Fainting	7	1
Abdominal Pain	4	2
Confusion	3	0
Hallucinations	3	1
Dry mouth	3	1
Vivid Dreams	2	0
Dyskinesias	2	5
Headache	2	1
The following events were reported once in either or both groups:		
Ache, generalized	1	0
Anxiety/Tension	1	1
Anemia	0	1
Diarrhea	1	0
Hair Loss	0	1
Insomnia	1	1
Lethargy	1	0
Leg pain	1	0
Low back pain	1	0
Malaise	0	1
Palpitations	1	0
Urinary Retention	1	0
Weight Loss	1	0

OVERDOSAGE:

Selegiline: No specific information is available about clinically significant overdoses with ELDEPRYL® (SELEGILINE HYDROCHLORIDE). However, experience gained during selegiline's development reveals that some individuals exposed to doses of 600 mg d,l selegiline suffered severe hypotension and psychomotor agitation.

Since the selective inhibition of MAO B by selegiline hydrochloride is achieved only at doses in the range recommended for the treatment of Parkinson's disease (e.g., 10 mg/day), overdoses are likely to cause significant inhibition of both MAO A and MAO B. Consequently, the signs and symptoms of overdose may resemble those observed with marketed non-selective MAO inhibitors [e.g., tranylcypromine (PARNATE), isocarboxazide (MARPLAN), and phenelzine (NARDIL)].

Overdose with Non-Selective MAO Inhibition: NOTE: This section is provided for reference; it does not describe events that have actually been observed with selegiline in overdose.

Characteristically, signs and symptoms of non-selective MAOI overdose may not appear immediately. Delays of up to 12 hours between ingestion of drug and the appearance of signs may occur. Importantly, the peak intensity of the syndrome may not be reached for upwards of a day following the overdose. Death has been reported following overdosage. Therefore, immediate hospitalization, with continuous patient observation and monitoring for a period of at least two days following the ingestion of such drugs in overdose is strongly recommended.

The clinical picture of MAOI overdose varies considerably; its severity may be a function of the amount of drug consumed. The central nervous and cardiovascular systems are prominently involved.

Signs and symptoms of overdosage may include, alone or in combination, any of the following: drowsiness, dizziness, faintness, irritability, hyperactivity, agitation, severe headache, hallucinations, trismus, opisthotonus, convulsions, and coma; rapid and irregular pulse, hypertension, hypotension and vascular collapse; precordial pain, respiratory depression and failure, hyperpyrexia, diaphoresis, and cool, clammy skin.

Treatment Suggestions for Overdose

NOTE: Because there is no recorded experience with selegiline overdose, the following suggestions are offered based upon the assumption that selegiline overdose may be modeled by non-selective MAOI poisoning. In any case, up-to-date information about the treatment of overdose can often be obtained from a certified Regional Poison Control Center. Telephone numbers of certified Poison Control Centers are listed in the Physician's Desk Reference (PDR).

Treatment of overdose with non-selective MAOIs is symptomatic and supportive. Induction of emesis or gastric lavage with instillation of charcoal slurry may be helpful in early poisoning, provided the airway has been protected against aspiration. Signs and symptoms of central nervous system stimulation, including convulsions, should be treated with diazepam, given slowly intravenously. Phenothiazine derivatives and central nervous system stimulants should be avoided. Hypotension and vascular collapse should be treated with intravenous fluids and, if necessary, blood pressure titration with an intravenous infusion of a dilute pressor agent. It should be noted that adrenergic agents may produce a markedly increased pressor response.

Respiration should be supported by appropriate measures, including management of the airway, use of supplemental oxygen, and mechanical ventilatory assistance, as required.

Body temperature should be monitored closely. Intensive management of hyperpyrexia may be required. Maintenance of fluid and electrolyte balance is essential.

DOSAGE AND ADMINISTRATION:

ELDEPRYL® (SELEGILINE HYDROCHLORIDE) is intended for administration to Parkinsonian patients receiving levodopa/carbidopa therapy who demonstrate a deteriorating response to this treatment. The recommended regimen for the administration of ELDEPRYL® (SELEGILINE HYDROCHLORIDE) is 10 mg per day administered as divided doses of 5 mg each taken at breakfast and lunch. There is no evidence that additional benefit will be obtained from the administration of higher doses. Moreover, higher doses should ordinarily be avoided because of the increased risk of side effects.

After two to three days of selegiline treatment, an attempt may be made to reduce the dose of levodopa/carbidopa. A reduction of 10 to 30% was achieved with the typical participant in the domestic placebo controlled trials who was assigned to selegiline treatment. Further reductions of levodopa/carbidopa may be possible during continued selegiline therapy.

Clinical and Morphometric Analysis of the Hypoplastic Corpus Callosum

G. Bradley Schaefer, MD; John B. Bodensteiner, MD; James N. Thompson, Jr, PhD; Don A. Wilson, MD

• A total of 307 children were evaluated over a 3-year period in our neurogenetics clinic. Review of their medical records demonstrated 26 patients with diagnoses of anomalies of the corpus callosum. Morphometric analysis was performed on those 23 patients qualitatively assessed as having a hypoplastic (small, but morphologically intact) corpus callosum. Morphometric data were compared with clinical correlates for each patient. From these data, we conclude that the hypoplastic corpus callosum is not a normal variant of development but rather an indicator of a more fundamental abnormality of cerebral development.

(*Arch Neurol.* 1991;48:933-936)

The corpus callosum is the major commissural pathway between the two cerebral hemispheres. Agenesis, or complete absence, of the corpus callosum (ACC) is widely recognized as a congenital anomaly that occurs frequently in children who are evaluated for mental retardation or developmental delay. Agenesis of the corpus callosum is also often associated with other anomalies of the nervous system and anomalies of other organs.[1] Partial ACC (PACC) is also believed to be a significant malformation. It is frequently associated with developmental delay, mental retardation, infancy-onset seizures, and a large variety of congenital anomalies.[2-4] There has been no general agreement, however, about the significance of a small, but intact, corpus callosum, which we will refer to as a hypoplastic corpus callosum (HCC). Representative examples of ACC, PACC, and HCC are shown in the Figure.

One of the reasons for this lack of consensus has been that the normal range of variation of the size of corpus callosum and the change in its relative size with increasing age had not been established for nonpostmortem brains. We have recently investigated the normal range of variation in this structure and have found that there are predictable age-associated changes in its postnatal development, presumably associated with myelination.[5] Interestingly, much of this change occurs after 10 years of age. Within a given age group, however, there is relatively little variation in the size of the corpus callosum in the midsagittal plane of imaging (Table 1).

We have identified 23 children who were evaluated over a 3-year period at the Childrens' Hospital of Oklahoma, Oklahoma City, and were qualitatively assessed as having an HCC. Morphometric analysis of corpus callosum size using the magnetic resonance imaging (MRI) scans of these patients has confirmed hypoplasia in 16. Quantitative analysis of the entire midsagittal brain section and review of patient records has allowed further subdivision into those with isolated HCC (3), those with HCC associated with other anomalies (11), and those with acquired HCC (2).

PATIENTS AND METHODS

Clinical Assessment

The neurogenetics clinic at Childrens' Hospital of Oklahoma has a formal protocol for evaluation of all patients. On initial visits, all patients under 4 years of age are evaluated for developmental milestones by a certified occupational therapist with the Peabody Motor Development Scale. The standardized developmental quotient (DQ) is recorded into the patient's chart. Many of the patients over 4 years old have already had formal intelligence-education testing completed before referral. Those tests done by qualified personnel (eg, public school system, local guidance center, or licensed private psychologists or child education specialists) are not repeated. All other patients are referred to the staff child psychologist for formal, age-appropriate developmental testing. In the clinic, all children are examined by pediatric neurologists and clinical geneticists. Chromosome analysis, including fragile X studies, urine metabolic screening, and MRI of the brain are performed on all patients referred for nonspecific neurologic and/or intellectual deficits.

Patient Selection

Medical records of all patients seen in the neurogenetics clinic between 1987 and 1989 (N = 307) were reviewed. Developmental anomalies of the corpus callosum were qualitatively diagnosed on inspection of the MRI scans of 26 of these patients. Three of these were found to have complete ACC or PACC and were excluded from further study. Morphometric analyses were done on the midsagittal MRI scans of the remaining 23 patients. Results were then compared with the clinical features of each patient.

Morphometric Analysis

The T_1-weighted (repetition time, 500 to 600 ms; echo time, 20 to 30 ms) midsagittal frame of each MRI scan was measured as described by Schaefer and coworkers.[5] Slice

Representative T_1-weighted midsagittal magnetic resonance imaging scans of the brain illustrating a spectrum of corpus callosum development: a, normal; b, partial agenesis; c, complete agenesis; and d, hypoplasia.

thickness ranged from 5 to 9 mm, with a maximum 20% interslice gap. The field of view was 20 to 24 cm; the matrix was 128×256 or 256×256. Scans were obtained from routine clinical MRI studies that utilized superconducting magnets operated at 1.5 tesla. The standard head coil provided by each manufacturer (S15 Gyroscan, Philips, Shelton, Conn, or Signa, General Electric, Milwaukee, Wis) was used. Visualization of the entire corpus callosum, the aqueduct of Sylvius, and the fourth ventricle was used to determine the midsagittal frame. Each selected frame was photographed and printed. Cross-sectional areas of selected structures were traced and cut into pieces. These areas were measured with a simple image analysis system (Ominicon System, Bausch & Lomb, Rochester, NY).

The cross-sectional area of the corpus callosum was expressed as a ratio to the area of the total intracranial vault (TICV) cross-sectional area of the midline brain. The TICV was delineated by a line along the outer perimeter of the cerebral cortex, along the anterior surface of the brain stem to the tip of the clivus, then from the anterior to the posterior margins of the foramen magnum, and finally to the attachment of the tentorium along the inner surface of the occipital bone. The size of the corpus callosum was expressed as a ratio relative to the TICV to correct for differences in the magnification in scanning and in photographic printing. Data obtained from selected patients were compared with previously determined age-specific normative data.[5] These normative data are summarized in Table 1.

RESULTS

The clinical and morphometric features of the 23 patients qualitatively identified as having an HCC are presented in Table 2. Three of these patients (Table 2, patients 1 through 3) had HCC, apparently as an isolated anomaly. All three had DQs below 2 SDs from the norm. No dysmorphic features, birth anomalies, or focal neurologic signs were noted in any of these patients, although one has a generalized seizure disorder (patient 2). The family histories were negative for other affected relatives with significant developmental delays.

Table 1.—Normative Data on CC/TICV Ratio in Midsagittal Plane*

Age Group, y	No.	CC/TICV Mean ± SD	CC/TICV Mean − 2 SDs
≤5	20	0.034 ± 0.010	0.013
6-10	20	0.037 ± 0.007	0.023
11-15	18	0.047 ± 0.014	0.019
16-20	27	0.046 ± 0.007	0.032

*CC/TICV indicates ratio of corpus callosum area to area of total intracranial vault (as defined in the text).

An additional 11 patients (Nos. 4 through 14) had an HCC along with other developmental anomalies of the brain. Many of these anomalies involved the midline developmental field. Examples of midline anomalies seen in our patients with HCC include septo-optic dysplasia (patients 4 and 9), absent septum pellucidum (patient 4), pituitary insufficiency (patient 11), and cerebellar vermal hypoplasia or an enlarged cisterna magna as determined by quantitative analysis of MRIs compared with normative data[5,6] (patients 5, 12, and 13).

Three patients (Nos. 5, 10, and 11) had an HCC in conjunction with anomalies of organ systems other than the central nervous system. Patient 5 had facial asymmetry, bilateral cleft lip and palate, anisocoria, up-slanting palpebral fissures, posterior rotation of the ears, maxillary hypoplasia, camptodactyly of the fingers, and a seizure disorder. Patient 10 had microcephaly, dysmorphic features, esotropia, right optic atrophy, a bifid scrotum, a deep sacral dimple, unilateral transverse palmar crease, deep plantar furrows, seizures, and findings compatible with a nonspecific generalized connective tissue disorder. Patient 11 was noted to have dysmorphic features, congenital heart disease, bilateral inguinal hernias, seizures, and congenital tightness of the heel cords. Pituitary insufficiency (central growth hormone deficiency) was also present in this patient, as noted above. No known syndrome or pattern of anomalies could be defined for the constellations of anomalies seen in these patients. Each patient had normal chromosome study results. All 11 patients had a DQ more than 2 SDs below the mean.

Patients 15 and 16 were noted to have HCC with obstructive hydrocephalus. One patient (No. 16) had hydrocephalus secondary to meningomyelocele; the other (No. 15) was a child with chronic hydrocephalus due to a posterior fossa neoplasm. Interestingly, both had a normal IQ or DQ, respectively.

Seven patients (Nos. 17 through 23) qualitatively assessed as having an

*HCC indicates hypoplastic corpus callosum; CC/TICV, the ratio of the corpus callosum area to the area of the total intracranial vault (as defined in the text).

HCC actually had a corpus callosum that was within 2 SDs of the normal average size for their age group (0 to 5 years old). All but two of these (patients 22 and 23) were, however, in the lower 7% of the age-corrected size range (mean ratio of corpus callosum area to TICV midline brain cross-sectional area, 0.034±0.010).

COMMENT

Agenesis of the corpus callosum, both partial and complete, is recognized as a major developmental anomaly frequently associated with functional deficits in mental ability.[7] In the past, a thin or small, but morphologically complete (hypoplastic), corpus callosum was thought to be a normal variant that could be attributed to a large degree of variability in the development of this structure. Morphometric analysis of normal individuals has now demonstrated that the size of the corpus callosum shows relatively little variation within a given age group.[5] Thus, it is possible to correlate statistically significant differences in the size of the corpus callosum with abnormalities of brain function. A preliminary accumulation of cases suggested to us that HCC is not a normal variant but, in fact, a significant finding suggestive of more global aberrant brain development.[8]

We initiated this study to investigate this issue further. A retrospective review was performed on all cases seen in our neurogenetics clinic over a 3-year period. Of the 307 patients seen during this period, three (1.0%) were noted to have complete ACC or PACC. This finding is comparable with the range of 0.2% to 2.9% found in other studies that have looked for these callosal anomalies in patient populations selected for developmental delays or mental retardation.[7,9]

We identified an additional 23 patients qualitatively assessed as having an HCC. This was confirmed by morphometric analysis in 16 (5.2% of the total sample). Anomalies of the corpus callosum, in general, thus represented a significant proportion (6%) of patients in our population, a population selected for developmental delays. We found no sex, race, or socioeconomic predilection in our patients with callosal anomalies.

All 16 patients with an HCC had mental retardation (DQ or IQ <2 SDs below the mean), with the exception of two patients (Nos. 15 and 16). Both of these patients were noted to have hydrocephalus, one associated with meningomyelocele and the other with a posterior fossa neoplasm. The occurrence of normal intellect with an HCC in these two patients is consistent with a mechanical postnatal thinning of this structure. Thus, in these cases, the small size of the corpus callosum would be a secondary phenomenon rather than an indicator of primary cerebral dysgenesis. This "secondary HCC" may be analogous to the HCC noted by Barkovich and Norman[4] in patients with cerebral palsy. In our patients, however, only one (patient 7) had a clinical picture suggestive of cerebral palsy. We would interpret these findings to suggest that, in the absence of indicators of factors that could influence callosal size after primary morphogenesis, HCC is an indicator of aberrant cerebral development.

The majority of patients with HCC (80%) had other developmental anomalies of the brain. Many of these anomalies were defects in midline structures, eg, hypoplasia of the cerebellar vermis, septo-optic dysplasia, absence of the septum pellucidum, pituitary insufficiency, or an enlarged cisterna magna. (A large cisterna magna is commonly classified as a "normal variant." However, we believe that it is not a normal variant but rather an extension of the spectrum of midline brain defects.[10] We will include it as such for purposes of discussion in this article.) The other nervous system anomalies seen in our patients with HCC largely included more generalized defects such as agyria, colpocephaly, holotelencephaly, and syringomyelia-syringobulbia.

Three patients had multiple congenital anomalies of organ systems other than the central nervous system. It is well recognized that patients with ACC and PACC have an increased incidence of anomalies outside of the central nervous system. Ocular, craniofacial, musculoskeletal, and cardiovascular are the most commonly reported associated anomalies.[1,4,11] The associated anomalies seen in our patients with HCC as detailed above are strikingly similar to those reported for ACC and PACC. The overall incidence of associated anomalies seen in our patients (3/16 [19%]) is also consistent with that reported for ACC and PACC. Further studies will be needed to determine if the scope and magnitude of associated anomalies in HCC are truly comparable with those seen in ACC and PACC.

In this study, we limited our analysis

of MRI scans to the T_1-weighted midsagittal slice. We acknowledge that there may be abnormalities of the corpus callosum that are not seen in the midline or not appreciated on T_1-weighted images. Thus, our estimate of the frequency of anomalies of the corpus callosum in patients with nonspecific mental retardation may be an underestimate. The advantage of limiting analysis to the midline is that it greatly simplifies the method (eg, complex volumetric measurements are avoided), which makes the technique more easily accessible to the clinician. Even though conservative, this type of analysis is likely to identify a large proportion of patients with abnormal events in brain development and to provide information that is of interest to the clinician.

We interpret these data to indicate that HCC is not a normal variant. Instead, HCC appears to be an indicator of a more fundamental abnormality of cerebral development. Furthermore, while no characteristic clinical neurologic syndrome can be identified in these patients, HCC is usually associated with subnormal intellectual function variable degree. Morphometric data helpful in providing objective measu of callosal size for correlation with t level of intellectual function. The in dence of this anomaly is unknown fo normative control group, but it is a re tively frequent anomaly in populati selected for developmental delay mental retardation.

This work was supported in part by a grant f the Presbyterian Health Foundation, Oklaho City.

In Tourette Syndrome

ORAP™

(pimozide) Tablets

Helps Patients Be Themselves*

- Excellent Symptom Control

"Pimozide produced significantly more improvement of symptoms and less akinesic adverse effects than haloperidol . . . Improvement of 70% or more was reported by 74% of patients on pimozide compared with 45% on haloperidol ($p < .02$), and 84% rated pimozide better overall than haloperidol."[1]

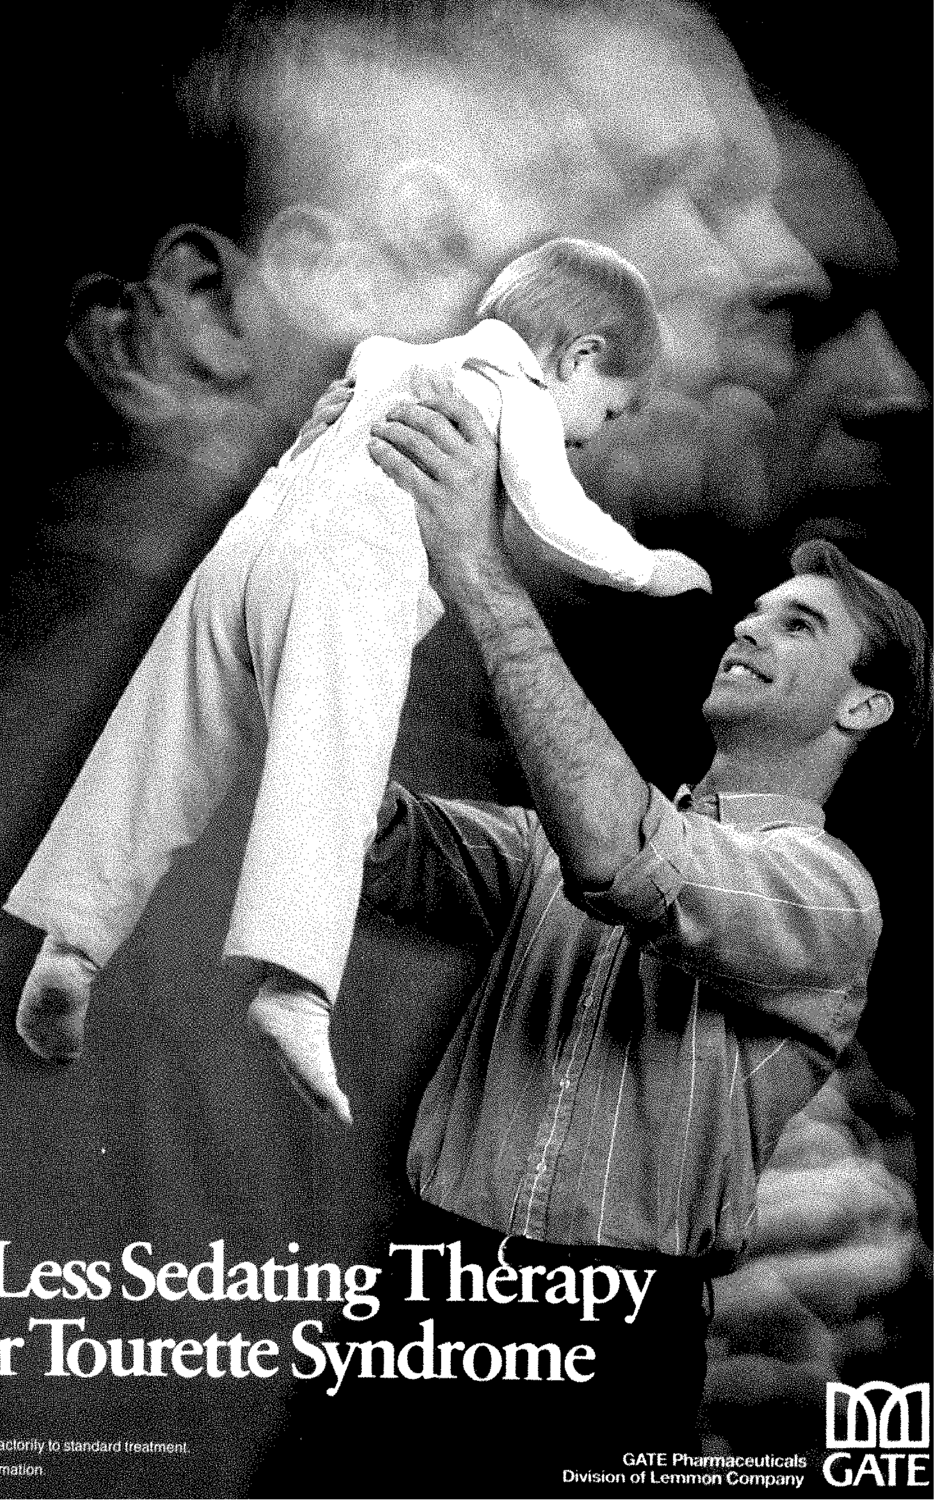
- Significantly Less Sedation than Haloperidol

In a double-blind, placebo-controlled study, "Pimozide was associated with lethargy or tiredness on significantly fewer days than haloperidol ($p < .01$), and this was reflected in greater immediate and long-term patient acceptance . . . ."[2]

- Documented Clinical Experience

Pimozide has been used in the treatment of Tourette Syndrome for over 10 years.[1]

For more information on ORAP, call 1-800-292-4283.



The Less Sedating Therapy for Tourette Syndrome

* ORAP is indicated for patients who have failed to respond satisfactorily to standard treatment.

Division of Lemmon Company
GATE

ORAP™ The Less Sedating Therapy for Tourette Syndrome

(pimozide) Tablets

INDICATIONS AND USAGE

ORAP (pimozide) is indicated for the suppression of motor and phonic tics in patients with Tourette's Disorder who have failed to respond satisfactorily to standard treatment. ORAP is not intended as a treatment of first choice nor is it intended for the treatment for tics that are merely annoying or cosmetically troublesome. ORAP should be reserved for use in Tourette's Disorder patients whose development and/or daily life function is severely compromised by the presence of motor and phonic tics.

Evidence supporting approval of pimozide for use in Tourette's Disorder was obtained in two controlled clinical investigations which enrolled patients between the ages of 8 and 53 years. Most subjects in the two trials were 12 or older.

CONTRAINDICATIONS

1. ORAP (pimozide) is contraindicated in the treatment of simple tics or tics other than associated with Tourette's Disorder.
2. ORAP should not be used in patients taking drugs that may, themselves, cause motor and phonic tics (e.g., pemoline, methylphenidate and amphetamines) until such patients have been withdrawn from these drugs to determine whether or not the drugs, rather than Tourette's Disorder, are responsible for the tics.
3. Because ORAP prolongs the QT interval of the electrocardiogram it is contraindicated in patients with congenital long QT syndrome, patients with a history of cardiac arrhythmias, or patients taking other drugs which prolong the QT interval of the electrocardiogram (see DRUG INTERACTIONS).
4. ORAP is contraindicated in patients with severe toxic central nervous system depression or comatose states from any cause.
5. ORAP is contraindicated in patients with hypersensitivity to it. As it is not known whether cross-sensitivity exists among the antipsychotics, pimozide should be used with appropriate caution in patients who have demonstrated hypersensitivity to other antipsychotic drugs.

WARNINGS

The use of ORAP (pimozide) in the treatment of Tourette's Disorder involves different risk/benefit considerations than when antipsychotic drugs are used to treat other conditions. Consequently, a decision to use ORAP should take into consideration the following: (see also PRECAUTIONS–Information for Patients).

Tardive Dyskinesia A syndrome consisting of potentially irreversible, involuntary, dyskinetic movements may develop in patients treated with antipsychotic drugs. Although the prevalence of the syndrome appears to be highest among the elderly, especially elderly women, it is impossible to rely upon prevalence estimates to predict, at the inception of antipsychotic treatment, which patients are likely to develop the syndrome. Whether antipsychotic drug products differ in their potential to cause tardive dyskinesia is unknown.

Both the risk of developing tardive dyskinesia and the likelihood that it will become irreversible are believed to increase as the duration of treatment is withdrawn. Antipsychotic treatment, itself, however, may suppress (or partially suppress) the signs and symptoms of the syndrome and thereby may possibly mask the underlying process. The effect that symptomatic suppression has upon the long-term course of the syndrome is unknown.

Given these considerations, antipsychotic drugs should be prescribed in a manner that is most likely to minimize the occurrence of tardive dyskinesia. Chronic antipsychotic treatment should generally be reserved for patients who suffer from a chronic illness that, 1) is known to respond to antipsychotic drugs, and, 2) for whom alternative, equally effective, but potentially less harmful treatments are not available or appropriate. In patients who do require chronic treatment, the smallest dose and the shortest duration of treatment producing a satisfactory clinical response should be sought. The need for continued treatment should be reassessed periodically.

If signs and symptoms of tardive dyskinesia appear in a patient on antipsychotics, drug discontinuation should be considered. However, some patients may require treatment despite the presence of the syndrome.

(For further information about the description of tardive dyskinesia and its clinical detection, please refer to ADVERSE REACTIONS and PRECAUTIONS–Information for Patients.)

Neuroleptic Malignant Syndrome (NMS) A potentially fatal symptom complex sometimes referred to as Neuroleptic Malignant Syndrome (NMS) has been reported in association with antipsychotic drugs. Clinical manifestations of NMS are hyperpyrexia, muscle rigidity, altered mental status (including catatonic signs) and evidence of autonomic instability (irregular pulse or blood pressure, tachycardia, diaphoresis, and cardiac dysrhythmias). Additional signs may include elevated creatine phosphokinase, myoglobinuria (rhabdomyolysis) and acute renal failure.

The diagnostic evaluation of patients with this syndrome is complicated. In arriving at a diagnosis, it is important to identify cases where the clinical presentation includes both serious medical illness (e.g., pneumonia, systemic infection, etc.) and untreated or inadequately treated extrapyramidal signs and symptoms (EPS). Other important considerations in the differential diagnosis include central anticholinergic toxicity, heat stroke, drug fever and primary central nervous system (CNS) pathology.

The management of NMS should include 1) immediate discontinuation of antipsychotic drugs and other drugs not essential to concurrent therapy, 2) intensive symptomatic treatment and medical monitoring, and 3) treatment of any concomitant serious medical problems for which specific treatments are available. There is no general agreement about specific pharmacological treatment regimens for uncomplicated NMS.

If a patient requires antipsychotic drug treatment after recovery from NMS, the potential reintroduction of drug therapy should be carefully considered. The patient should be carefully monitored, since recurrences of NMS have been reported.

Hyperpyrexia, not associated with the above symptom complex, has been reported with other antipsychotic drugs.

Other Sudden, unexpected deaths have occurred in experimental studies of conditions other than Tourette's Disorder. These deaths occurred while patients were receiving dosages in the range of 1 mg per kg. One possible mechanism for such deaths is prolongation of the QT interval predisposing patients to ventricular arrhythmia. An electrocardiogram should be performed before ORAP treatment is initiated and periodically thereafter, especially during the period of dose adjustment.

ORAP may have a tumorigenic potential. Based on studies conducted in mice, it is known that pimozide can produce a dose related increase in pituitary tumors. The full significance of this finding is not known, but should be taken into consideration in the physician's and patient's decisions to use this drug product. This finding should be given special consideration when the patient is young and chronic use of pimozide is anticipated. (see PRECAUTIONS–Carcinogenesis, Mutagenesis, Impairment of Fertility).

PRECAUTIONS

General ORAP (pimozide) may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks, such as driving a car or operating machinery, especially during the first few days of therapy.

ORAP produces anticholinergic side effects and should be used with caution in individuals whose conditions may be aggravated by anticholinergic activity.

ORAP should be administered cautiously to patients with impairment of liver or kidney function, because it is metabolized by the liver and excreted by the kidneys.

Antipsychotics should be administered with caution to patients receiving anticonvulsant medication, with a history of seizures, or with EEG abnormalities, because they may lower the convulsive threshold. If indicated, adequate anticonvulsant therapy should be maintained concomitantly.

Laboratory Tests An ECG should be done at baseline and periodically thereafter throughout the period of dose adjustment. Any indication of prolongation of QT_c interval beyond an absolute limit of 0.47 seconds (children) or 0.52 seconds (adults), or more than 25% above the patient's original baseline should be considered a basis for stopping further dose increase (see CONTRAINDICATIONS) and considering a lower dose.

Since hypokalemia has been associated with ventricular arrhythmias, potassium insufficiency, secondary to diuretics, diarrhea, or other cause, should be corrected before ORAP therapy is initiated and normal potassium maintained during therapy.

Drug Interactions Because ORAP prolongs the QT interval of the electrocardiogram, an additive effect on QT interval would be anticipated if administered with other drugs, such as phenothiazines, tricyclic antidepressants or antiarrhythmic agents, which prolong the QT interval. Such concomitant administration should not be undertaken (see CONTRAINDICATIONS).

ORAP may be capable of potentiating CNS depressants, including analgesics, sedatives, anxiolytics, and alcohol

Carcinogenesis, Mutagenesis, Impairment of Fertility Carcinogenicity studies were conducted in mice and rats. In mice, pimozide causes a dose-related increase in pituitary and mammary tumors.

When mice were treated for up to 18 months with pimozide, pituitary gland changes developed in females only. These changes were characterized as hyperplasia at doses approximating the human dose and adenoma at doses about fifteen times the maximum recommended human dose on a mg per kg basis. The mechanism for the induction of pituitary tumors in mice is not known

Mammary gland tumors in female mice were also increased, but these tumors are expected in rodents treated with antipsychotic drugs which elevate prolactin levels. Chronic administration of an antipsychotic also causes elevated prolactin levels in humans. Tissue culture experiments indicate that approximately one-third of human breast cancers are prolactin-dependent in vitro, a factor of potential importance if the prescription of these drugs is contemplated in a patient with a previously detected breast cancer. Although disturbances such as galactorrhea, amenorrhea, gynecomastia, and impotence have been reported with antipsychotic drugs, the clinical significance of elevated serum prolactin levels is unknown for most patients. Neither clinical studies nor epidemiologic studies conducted to date have shown an association between chronic administration of these drugs and mammary tumorigenesis. The available evidence, however, is considered too limited to be conclusive at this time.

In a 24 month carcinogenicity study in rats, animals received up to 50 times the maximum recommended human dose. No increased incidence of overall tumors or tumors at any site was observed in either sex. Because of the limited number of animals surviving this study, the meaning of these results is unclear.

Pimozide did not have mutagenic activity in the Ames test with four bacterial test strains, in the mouse dominant lethal test or in the micronucleus test in rats.

Reproduction studies in animals were not adequate to assess all aspects of fertility. Nevertheless, female rats administered pimozide had prolonged estrus cycles, an effect also produced by other antipsychotic drugs.

Pregnancy Category C. Reproduction studies performed in rats and rabbits at oral doses up to 8 times the maximum human dose did not reveal evidence of teratogenicity. In the rat, however, this multiple of the human dose resulted in decreased pregnancies and in the retarded development of fetuses. These effects are thought to be due to an inhibition or delay in implantation which is also observed in rodents administered other antipsychotic drugs. In the rabbit, maternal toxicity, mortality, decreased weight gain, and embryotoxicity including increased resorptions were dose related. Because animal reproduction studies are not always predictive of human response, pimozide should be given to a pregnant woman only if the potential benefits of treatment clearly outweigh the potential risks

Labor and Delivery This drug has no recognized use in labor or delivery.

Nursing Mothers It is not known whether pimozide is excreted in human milk. Because many drugs are excreted in human milk and because of the potential for tumorigenicity and unknown cardiovascular effects in the infant, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use Although Tourette's Disorder most often has its onset between the ages of 2 and 15 years, information on the use and efficacy of ORAP in patients less than 12 years of age is limited.

Because its use and safety have not been evaluated in other childhood disorders, ORAP is not recommended for use in any condition other than Tourette's Disorder.

ADVERSE REACTIONS

General: Extrapyramidal Reactions. Neuromuscular (extrapyramidal) reactions during the administration of ORAP (pimozide) have been reported frequently, often during the first few days of treatment. In most patients, these reactions involved Parkinson-like symptoms which, when first observed, were usually mild to moderately severe and usually reversible.

Other types of neuromuscular reactions (motor restlessness, dystonia, akathisia, hyperreflexia, opisthotonos, oculogyric crises) have been reported far less frequently. Severe extrapyramidal reactions have been reported to occur at relatively low doses. Generally the occurrence and severity of most extrapyramidal symptoms are dose related since they occur at relatively high doses and have been shown to disappear or become less severe when the dose is reduced. Administration of antiparkinson drugs such as benztropine mesylate or trihexyphenidyl hydrochloride may be required for control of such reactions. It should be noted that persistent extrapyramidal reactions have been reported and that the drug may have to be discontinued in such cases.

Withdrawal Emergent Neurological Signs: Generally, patients receiving short term therapy experience no problems with abrupt discontinuation of antipsychotic drugs. However, some patients on maintenance treatment experience transient dyskinetic signs after abrupt withdrawal. In certain of these cases the dyskinetic movements are indistinguishable from the syndrome described below under 'Tardive Dyskinesia' except for duration. It is not known whether gradual withdrawal of antipsychotic drugs will reduce the rate of occurrence of withdrawal emergent neurological signs but until further evidence becomes available, it seems reasonable to gradually withdraw use of ORAP.

Tardive Dyskinesia: ORAP may be associated with persistent dyskinesias. Tardive dyskinesia, a syndrome consisting of potentially irreversible, involuntary, dyskinetic movements, may appear in some patients on long-term therapy or may occur after drug therapy has been discontinued. The risk appears to be greater in elderly patients on high-dose therapy, especially females. The symptoms are persistent and in some patients appear irreversible. The syndrome is characterized by rhythmical involuntary movements of tongue, face, mouth or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements). Sometimes these may be accompanied by involuntary movements of extremities and the trunk.

There is no known effective treatment for tardive dyskinesia; antiparkinson agents usually do not alleviate the symptoms of this syndrome. It is suggested that all antipsychotic agents be discontinued if these symptoms appear. Should it be necessary to reinstitute treatment, or increase the dosage of the agent, or switch to a different antipsychotic agent, this syndrome may be masked.

It has been reported that fine vermicular movement of the tongue may be an early sign of tardive dyskinesia and if the medication is stopped at that time the syndrome may not develop.

Electrocardiographic Changes: Electrocardiographic changes have been observed in clinical trials of ORAP in Tourette's Disorder and schizophrenia. These have included prolongation of the QT interval, flattening, notching and inversion of the T wave and the appearance of U waves. Sudden, unexpected deaths and grand mal seizure have occurred at doses above 20 mg/day

Neuroleptic Malignant Syndrome: Neuroleptic malignant syndrome (NMS) has been reported with ORAP. (See WARNINGS for further information concerning NMS.)

Hyperpyrexia: Hyperpyrexia has been reported with other antipsychotic drugs.

Clinical Trials The following adverse reaction tabulation was derived from 20 patients in a 6 week long placebo controlled clinical trial of ORAP in Tourette's Disorder.

Body System/ Adverse Reaction	Pimozide (N = 20)	Placebo (N = 20)
Body as a Whole		
Headache	1	2
Gastrointestinal		
Dry mouth	5	1
Diarrhea	1	0
Nausea	0	2
Vomiting	0	1
Constipation	4	2
Eructations	0	1
Thirsty	1	0
Appetite increase	1	0
Endocrine		
Menstrual disorder	0	1
Breast secretions	0	1
Musculoskeletal		
Muscle cramps	0	1
Muscle tightness	3	0
Stooped posture	2	0
CNS		
Drowsiness	7	3
Sedation	14	5
Insomnia	2	2
Dizziness	0	1
Akathisia	8	0
Rigidity	2	0
Speech disorder	2	0
Handwriting change	1	0
Akinesia	8	0
Psychiatric		
Depression	2	3
Excitement	0	1
Nervous	1	0
Adverse behavior effect	5	0
Special Sense		
Visual disturbance	4	0
Taste change	1	0
Sensitivity of eyes to light	1	0
Decreased accommodation	4	1
Spots before eyes	0	1
Urogenital		
Impotence	3	0

Because clinical investigational experience with ORAP in Tourette's Disorder is limited, uncommon adverse reactions may not have been detected. The physician should consider that other adverse reactions associated with antipsychotics may occur.

Other Adverse Reactions In addition to the adverse reactions listed above, those listed below have been reported in U.S. clinical trials of ORAP in conditions other than Tourette's Disorder.

Body as a Whole: Asthenia, chest pain, periorbital edema
Cardiovascular/Respiratory: Postural hypotension, hypotension, hypertension, tachycardia, palpitations
Gastrointestinal: Increased salivation, nausea, vomiting, anorexia, GI distress
Endocrine: Loss of libido
Metabolic/Nutritional: Weight gain, weight loss
Central Nervous System: Dizziness, tremor, parkinsonism, fainting, dyskinesia
Psychiatric: Excitement
Skin: Rash, sweating, skin irritation
Special Senses: Blurred vision, cataracts
Urogenital: Nocturia, urinary frequency

Postmarketing Reports The following experiences were described in spontaneous postmarketing reports. These reports do not provide sufficient information to establish a clear causal relationship with the use of ORAP.

Hematologic: Hemolytic anemia

OVERDOSAGE

In general, the signs and symptoms of overdosage with ORAP (pimozide) would be an exaggeration of known pharmacologic effects and adverse reactions, the most prominent of which would be: 1) electrocardiographic abnormalities, 2) severe extrapyramidal reactions, 3) hypotension, 4) a comatose state with respiratory depression.

In the event of overdosage, gastric lavage, establishment of a patent airway and, if necessary mechanically-assisted respiration are advised. Electrocardiographic monitoring should commence immediately and continue until the ECG parameters are within the normal range. Hypotension and circulatory collapse may be counteracted by use of intravenous fluids, plasma, or concentrated albumin, and vasopressor agents such as metaraminol, phenylephrine and norepinephrine. Epinephrine should not be used. In case of severe extrapyramidal reactions, antiparkinson medication should be administered. Because of the long half-life of pimozide, patients who take an overdose should be observed for at least 4 days. As with all drugs, the physician should consider contacting a poison control center for additional information on the treatment of overdose

DOSAGE AND ADMINISTRATION

Reliable dose response data for the effects of ORAP (pimozide) on tic manifestations in Tourette's Disorder patients below the age of twelve are not available. Consequently, the suppression of tics by ORAP requires a slow and gradual introduction of the drug. The patient's dose should be carefully adjusted to a point where the suppression of tics and the relief afforded is balanced against the untoward side effects of the drug.

An ECG should be done at baseline and periodically thereafter, especially during the period of dose adjustment (see WARNINGS and PRECAUTIONS–Laboratory Tests).

In general, treatment with ORAP should be initiated with a dose of 1 to 2 mg a day in divided doses. The dose may be increased thereafter every other day. Most patients are maintained at less than 0.2 mg/kg per day, or 10 mg/day, whichever is less. Doses greater than 0.2 mg/kg/day or 10 mg/day are not recommended.

Periodic attempts should be made to reduce the dosage of ORAP to see whether or not tics persist at the level and extent first identified. In attempts to reduce the dosage of ORAP, consideration should be given to the possibility that increases of tic intensity and frequency may represent a transient, withdrawal related phenomenon rather than a return of disease symptoms. Specifically, one to two weeks should be allowed to elapse before one concludes that an increase in tic manifestations is a function of the underlying disease syndrome rather than a response to drug withdrawal. A gradual withdrawal is recommended in any case.

HOW SUPPLIED

ORAP (pimozide) 2 mg tablets, white, scored, imprint "LEMMON" and "ORAP-2"—NDC 57844-187-01, bottles of 100.

Dispense in tight, light-resistant containers as defined in the official compendium.

Alcohol-Induced Brain Changes in Dogs

Lawrence A. Hansen, MD; Benjamin H. Natelson, MD; Cynthia Lemere, MS; Wendell Niemann, DVM;
Richard De Teresa; Timothy J. Regan, MD; Eliezer Masliah, MD; Robert D. Terry, MD

• We studied the neuropathologic effects of chronic alcohol ingestion on the brains of healthy, well-nourished, male mongrel dogs. Five experimental dogs were provided 36% of their calories as ethyl alcohol for 1 year. Following killing, their brains were weighed, photographed, sectioned, and processed for computerized morphometric determinations of ventricular size, cortical thickness, and neocortical neuron and glial cell populations. Compared with a similarly handled control group, the alcoholic dog brains showed lateral ventricular enlargement, cortical thinning in the temporal lobe only, and fewer glial cells in the temporal and frontal cortices. There were no statistically significant differences between the alcoholic and control groups in brain weight, frontal or parietal cortical thickness, or neocortical neuron populations. These results imply a disproportionate vulnerability of white matter to the damaging effects of alcohol with consequent lateral ventricular enlargement, and some regional variation in neocortical susceptibility to alcohol-induced cortical thinning and glial cell loss. In general, such changes are consistent with those described in neuroradiologic imaging studies of human alcoholics.

(*Arch Neurol*. 1991;48:939-942)

Every neurologist is aware of an association between alcoholism and mental function, and indeed a recent review of causes of dementia notes that alcoholism is diagnosed as the etiologic factor in 7% of all demented patients.[1] Supporting the idea of an association between alcoholism and brain disease are several radiologic[2] and pathologic[3-5] studies that show hydrocephalus and brain shrinkage by computed tomography in alcoholic patients.

Unfortunately, such studies do not allow one to decide whether the relationship between alcoholism and cognitive dysfunction is merely associative or whether the relationship is one of cause and effect. After all, it is known that alcoholics have a number of other major risk factors, which can summate as clinical dementia. These include (1) poor nutrition that can produce Wernicke-Korsakoff syndrome, (2) repeated head trauma related directly or indirectly to drinking that can produce the punch drunk syndrome, and (3) repeated seizures (ie, alcohol withdrawal seizures or rum fits) that can produce head trauma and/or cerebral anoxia.

Harper et al[6] have collected additional neuropathologic data from humans in an effort to clarify the question of what alcohol does to the brain. They showed that frank alcoholism was associated with significantly larger ventricular volume than control subjects drinking less than 20 g of ethyl alcohol per day. Importantly, moderate drinkers, those drinking 30 to 80 g per day, had ventricular volumes that were intermediate between those of the control subjects and those of the alcoholics. This study suggests that alcohol may be a primary cerebrotoxin. However, the classification of "moderate" or "alcoholic" was always done retrospectively, and so one can never be sure about the patient's drinking status.

Unfortunately, in understanding the cause of any human disease, research with humans rarely allows one to go definitively beyond associations among variables to cause-and-effect relationships. One way to circumvent this problem is to use animal models—a tactic we have chosen. This allows one to eliminate extraneous causes of brain disease by controlling dietary and medical conditions in experimental animals.

In this study, we used 2- to 3-year-old healthy male mongrel dogs to assess the neuropathologic effects of a high alcohol diet in an experimental group consuming 36% of their daily calories as ethyl alcohol. The brains of the alcoholic and control dogs were fixed, sectioned, photographed, and examined with computerized morphometric methods to determine ventricular sizes and neocortical neuron and glial populations in various lobes. Since the experimental alcoholic and control dogs were fed calorically similar diets and maintained under identical conditions, any neuropathologic changes found could be attributed to the effects of alcohol rather than to nutritional deficiencies. We obtained results generally comparable with those found using neuroradiologic imaging techniques in the analysis of human alcoholic brains, ie, ventricular enlargement presumably caused by reduced white matter volume and comparatively subtle neocortical alterations.

MATERIALS AND METHODS

Male mongrel dogs, 2 to 3 years of age, were selected from animals in good health and divided into control and chronic ethyl alcohol groups. The dogs in the two groups were matched well for size, with those in the alcohol group having weights ranging from 25.3 to 32.0 kg (mean, 28.6 kg), and with those in the control group having weights ranging from 22.0 to 32.0 kg (mean, 26.7 kg).

All were vaccinated against distemper, hepatitis, and leptospirosis, and were housed in individual cages. They were free of intestinal parasites and clinical evidence of disease for a period of 6 to 8 weeks of observation before admission to the study. Blood samples were negative for heartworms, and both hematocrit and serum protein levels were initially normal. The control dogs received a diet sufficient to maintain body weight in the adult animals (260.4 J/kg), consisting of 26% of calories as protein, 12% fat, and 62% carbohydrate. The corresponding values in the alcoholic group were 16.6% of calories as protein, 7.7% lipid, and 39.7% carbohydrate, which met the minimum standard for maintaining a normal nutritional state.[7]

After 4 weeks of progressively increasing doses, animals consuming virtually all the ethyl alcohol provided were admitted to the experimental group. There were five dogs in the control group and five in the alcohol group. The chronic ethyl alcohol animals were provided 36% of calories as ethyl alcohol for 6 days per week. On the seventh day, the nonalcoholic control diet was provided. Due to difficulties in feeding by gastric tube for prolonged periods, the ethyl alcohol (USP, US Industrial Chemicals, Division of National Distillers and Chemical Corp, New York, NY) was administered with the food. Apart from obvious sedation related to the alcohol meal, the experimental animal could not be differentiated from the control dogs. After 11 to 12 months the animals were anesthetized with chloralose following an overnight fast. Electrophysiologic and metabolic studies were performed over the subsequent 3 hours, while these closed-chest animals were ventilated through an endotracheal tube with 40% oxygen. Blood was collected for assay of hematocrit, albumin, and electrolyte concentrations. In terms of these blood indexes, good nutrition was documented in the alcohol-fed group, since mean values for albumin, sodium, potassium, chloride, and hematocrit did not differ significantly from those of the control dogs. At termination the chest was opened, and the heart was arrested with iced Ringer's solution. Both common carotids were clamped, cannulated, chilled, heparinized, and perfused with saline followed by formaldehyde solution. The calvarium was then opened and the brain removed and stored in 4% formaldehyde solution for several months.

The brains were then photographed and weighed both with and without the brain stems and cerebellums attached. Tissue blocks for neocortical morphometry were taken from the left hemisphere. The frontal lobe section was from the pars anterior of the sigmoid gyrus in the precoronal region, the territory of the motor cortex. The temporal lobe section was from the pars posterior of the sylvian gyrus, posterior to the sylvian fissure. The parietal lobe section was from the junction of the gyrus suprasylvius medium and gyrus suprasylvius posterior.[8] It can be contended, on cytoarchitectural criteria, that this brain region is actually a part of the temporal lobe rather than the parietal lobe. We chose this area, nevertheless, because on gross inspection of the lateral surface of the brain it most closely corresponded to the inferior parietal lobule in the human brain. In selecting these three neocortex sections for analysis, we were attempting to parallel those used in morphometric studies of the human brain concerning normal aging, Alzheimer's disease, and alcoholism. Specifically, the brain regions analyzed in those investigations are the midfrontal cortex, superior temporal gyrus, and inferior parietal area.

Two coronal slices were made to evaluate the cross-sectional areas of the ventricular systems. The anterior section was made through the temporal tips, perpendicular to the long fronto-occipital axis of the specimen. The posterior level was made at or near the splenium of the corpus callosum. To evaluate the size of the fourth ventricle, a section was taken through the pontomesencephalic junction at the level of the genu of the facial nerve. Using a computerized image analysis system (Quantimet 970), the black-and-white photographs of the brain slices were digitized into computer images, allowing measurement of ventricular areas at the three levels.

Tissue blocks taken from frontal, temporal, and parietal lobes were oriented carefully to ensure that the cortex along the sulcus was cut perpendicular to the pial surface. Following paraffin embedding, 20-μm-thick cresyl violet preparations were made. Counts were performed with the computerized image analysis system in a rectangle of cortex measuring 360 μm in width along the pial surface extending through the full cortical thickness. The microscopic image was visualized on a video screen that allowed manual editing of the computer image. Contiguous cells were separated, vascular elements and artifacts were excluded, and cells whose cytoplasmic outlines were incompletely detected (by the computerized counting program) were filled in before measurement.

All cresyl violet-stained cells in the neocortex were classified into size groups according to the areas of the perikarya in square microns. To determine which cells were neurons and which cells were glia, we performed the following analysis using both alcoholic and normal control dog brain sections from the frontal and parietal lobes. Moving from the pial surface to the white matter through the counted neocortical area, all cells that could be definitely identified as neurons on the basis of nuclear morphology, nucleolar prominence, Nissl substance, and pyramidal shape were measured and counted. The same cortical area was then counted again, only this time those cells that could be definitely identified as either astrocytes or oligodendroglia were measured and counted. Morphologic criteria for these decisions were nuclear shape, chromatin pattern, and cytoplasmic contours. These determinations were performed in four cases (two normal subjects and two alcoholics) for both neurons and glia. We found that 98% of all cells that could be definitively identified as neurons were 80 μm^2 or greater in cross-sectional area, while 99% of all cells definitively identifiable as glia were less than 80 μm^2, and 95% of these were less than 60 μm^2. There was, therefore, almost no overlap between neurons and glia, and cell size/cell type correlations could be made with confidence. We made a similar attempt to distinguish between oligodendroglia and astrocytes on the basis of cross-sectional area. Despite the fact that oligodendroglia were, on average, smaller than astrocytes, these two cell types showed too much size overlapping to allow confident distinction between them based on cell surface area. For the purposes of this study, we therefore lumped oligodendroglia, astrocytes, and microglia in the single category of glial cells.

RESULTS

Statistical comparisons between data from alcoholics and controls were made by averaging the measured variables for each group and using the two-tailed Student *t* test. Significance was assigned if the *P* value was less than .05. The results are given in Tables 1 and 2. Significant differences between alcoholic and control brains were found in only five of 16 measured variables. Compared with the control brains, the alcoholic specimens had larger lateral ventricles and cerebral aqueducts, a thinner cortical ribbon in the temporal section only, and fewer glial cells in the temporal and frontal cortices. The ventricular enlargement was most prominent posteriorly, at the level of the splenium of the corpus callosum (Figure). Lateral ventricle surface areas in four of five alcoholic dogs exceeded the mean lateral ventricle size for the five control dogs by more than 1 SD. There were no statistically significant differences in whole brain weights, cerebral weights, or the weights of the combined brain stem and cerebellum. There was no difference in frontal or parietal cortical thickness, and neuron populations in all neocortical regions were undiminished in the alcoholic group. We did not compare mean neuron sizes in the two groups. There was no statistically significant enlargement of the third or fourth ventricles in the alcoholic compared with control brains, and glial populations in the parietal section were the same.

COMMENT

To our knowledge, this study is the first to show definitively that alcohol can directly harm the brain and thus conceivably produce dementia. These results imply that white matter rather than gray matter bears the brunt of the neuropathologic damage caused by high alcohol intake. Neuron populations from all neocortical regions were undiminished in the alcoholic compared with the control brains, and the cortex showed significant thinning only in the temporal lobe. However, the lateral ventricles and cerebral aqueduct were dilated, and this must be interpreted as reflecting reduced white matter volume, since the cortex showed only slight regional thinning. Interestingly, there is an apparent loss of glial cells (either astrocytes or oligodendroglia) in both the frontal and temporal cortices.

These data in a nonhuman animal model confirm the findings of many neuroradiologic and morphometric studies of alcoholic human brains. Some investigators have found diminished brain weights among alcoholics,[9] but others have found no significant diminution in mean brain weight compared with controls.[5] Brain weights did not differ significantly in our study between the alcoholics and the control group. Many investigators have found disproportionate atrophy of cerebral white matter compared with gray matter among alcoholics.[3-5,9-12]

Our finding of greater temporal lobe changes (cortical thinning and loss of glial cells) also supports the concept of regional variation in the severity of neuropathologic effects of alcohol. It has long been known that alcohol causes neuron loss in the rostral cerebellar vermis while leaving other regions of cerebellum relatively unaffected. Similarly, quantitative morphometric studies of human alcoholic brains have shown some neuron loss in the superior frontal cortex, while neuron populations were undiminished in the motor cortex.[4] Nevertheless—at least over the time span of alcohol exposure used in this study—nerve cell loss per se does not appear to be a major pathologic effect of alcohol. Rather, neuronal shrinkage could occur while the white matter volume is diminishing. We are unable to comment on neuronal shrinkage as such, since our computer program serves to measure cells and assign them to size categories, but not to determine average cell sizes within those categories. Absence of irreversible cell loss secondary to alcohol consumption is, however, supported by many studies showing reversibility, both of ventricular enlargement and of deficits in psychologic testing evidenced by alcoholics.[11]

Table 1.—Mean Brain Weights and Ventricular Sizes*

	Control Subjects (SD) (N = 5)	Alcoholics (SD) (N = 5)	P

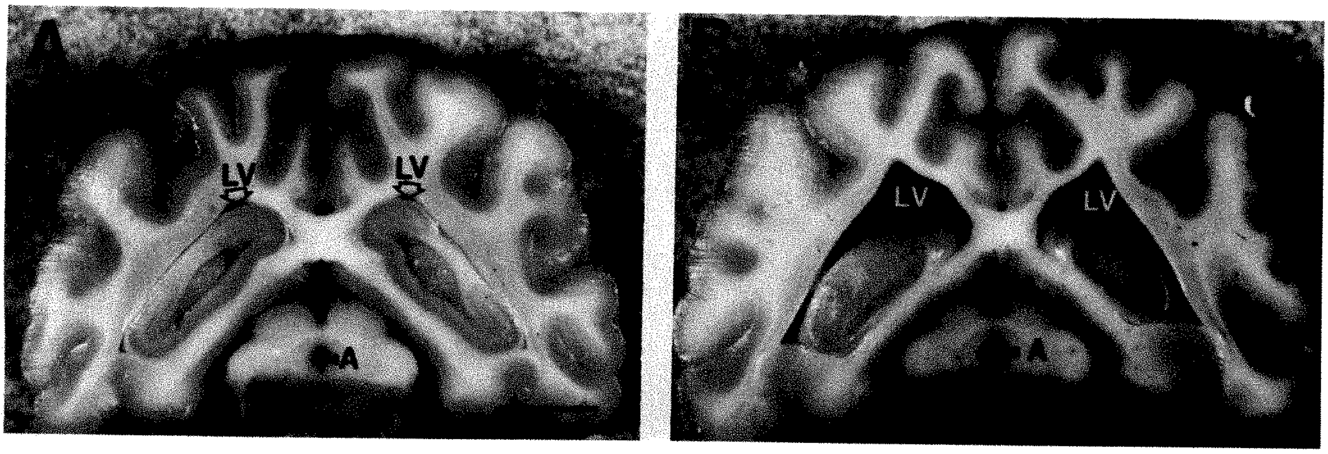
*Neurons are all cells 80 μm^2 or larger; glia are all cells less than 80 μm^2; NS indicates not significant.

The cause of reduced white matter volume is speculative. If axons shrink in response to chronic alcohol ingestion, loss of axonal caliber may be accompanied by thinning of myelin sheaths and resulting white matter shrinkage. Alternatively, our finding of diminished glial cells in the neocortex may reflect damage to oligodendroglia, and suggests that these cells may be affected directly in the underlying white matter. Experimental models of ethyl alcohol-induced neurotoxicity have shown abnormal myelin development in rats exposed to alcohol in utero, with delayed myelination and reduced accumulation of brain myelin.[13] Alcohol consumption in the first two trimesters increases the risk of producing children

Representative brains from the control group (left) and the alcoholic group (right). At the level of the splenium of the corpus callosum, both the lateral ventricles and the cerebral aqueduct were enlarged in the alcoholics. LV indicates lateral ventricles; A, aqueduct.



whose development is delayed and growth lags permanently. Alcohol in the third trimester and during lactation may increase the risk of impaired normal development of brain myelin. A study of alcoholic brains in patients without Wernicke's disease showed diminished myelin in the mamillary bodies compared with controls, but normal amounts of myelin in dorsal thalamus, quadrigeminal plate, and cerebellar vermis. These data were interpreted as reflecting regional variation in susceptibility to alcohol damage and as implying a specific myelin vulnerability.[14] Further support for the concept of alcohol myelin toxicity comes from a study showing delayed latencies of auditory brain-stem potentials in alcoholics compared with controls. These findings were considered suggestive of possible demyelination of auditory tracts in alcoholics.[15] Simple dehydration in alcoholism as an explanation for the white matter loss does not seem to be an operative mechanism. In fact, neurochemical studies of white matter in alcoholics have shown decreased lipid content and increased water content.[6] White matter is about 70% water, 20% lipid, and 10% protein, and most of the lipid and protein are combined to form membranes, myelin in particular. When the water content increases the lipid content decreases, and this pattern of change can be seen in both demyelinating conditions and wallerian degeneration.[6] The increased white matter water content in alcoholics could be due either to axonal loss (wallerian degeneration) or to more subtle primary myelin alterations. Whether the neurotoxic effects of alcohol in the centrum semiovalae are attributable to damage to axons primarily or oligodendroglial cells is presently undetermined.

Further studies using this dog model would be necessary to determine if the alcohol-induced ventricular dilatation is reversible by abstinence. Nevertheless, the otherwise relatively mild effects of high alcohol intake seen in this study as well as the reversibility of the brain shrinkage seen in human alcoholics, are cause for optimism, since they imply that abandonment of the alcoholic life-style may result in functional and in anatomic reconstitution of an essentially normal brain. The neuropathologic consequences of continued alcohol use beyond the duration used herein remain unknown. The fact that frank dementia does eventually occur in the heavy drinker suggests the presence of greater neuropathologic changes than those seen in our animal model.

Millions Go Widely Untreated

A Depression Teleconference sponsored by the American Medical Association and the National Institute of Mental Health

According to the National Institute of Mental Health, over 10 million Americans will suffer from depression at least once in their lives.

Most patients are not seen by mental health professionals, but by primary care physicians.

The American Medical Association and the National Institute of Mental Health are sponsoring a three-part teleconference at *no cost* to you, offering the primary care physician important information on diagnosing and treating depression among patients.

You are invited, and encouraged, to attend this important series. There will be numerous satellite link-ups at hospitals throughout the United States. Call now to register and to find out the location nearest you.

Schedule:
Program One:
Epidemiology, Etiology, Diagnosis
October 24, 1991
2:00-3:30 pm (ET)

Program Two:
Treatment: Pharmacology and Psychotherapy
November 21, 1991
2:00-3:30 pm (ET)

Program Three:
Depression Among Special Populations
December 11, 1991
2:00-3:30 pm (ET)

To register for this *free* teleconference and to find out the location nearest you, call TOLL-FREE 1-800-262-3211.

The American Medical Association is accredited by the Accreditation Council for Continuing Medical Education to sponsor continuing medical education for physicians. The American Medical Association designates this continuing medical education activity for 1.5 credit hours of Category 1 of the Physician's Recognition Award of the American Medical Association.

This program has been reviewed and is acceptable for 1.5 prescribed hours by the American Academy of Family Physicians.

The American College of Obstetricians and Gynecologists has assigned 2 cognates (formal learning) to this program.

THE FOURTH OKLAHOMA
NEURO-OPHTHALMOLOGY COURSE

THE BASICS OF NEURO-OPHTHALMOLOGY

Emphasizing the following: The Neuro-Ophthalmologic Exam, The Pupil, Visual Loss Workup, Optic Nerve Disorders, Diplopia Workup, Motility Disorders, Headache, Visual Fields, Chiasmal and Parasellar Disease, Thyroid Eye Disease, Myasthenia Gravis, Strokes, Pseudotumor Cerebri, and other entities.

OCTOBER 24-25, 1991
OKLAHOMA CITY, OKLAHOMA
WATERFORD HOTEL

Lower Extremity Motor Evoked Potentials in Multiple Sclerosis

Seth M. Jones, MD; Leopold J. Streletz, MD;
Vicki E. Raab, MD; Robert L. Knobler, MD, PhD; Fred D. Lublin, MD

• Transcranial magnetic stimulation was performed on 25 patients with definite multiple sclerosis. Motor evoked potentials were recorded from the anterior tibial muscle. Central motor conduction time was calculated using the equation $(F + M - 1)/2$ by stimulation of the common peroneal nerve. Motor evoked potentials were capable of detecting subclinical pyramidal tract lesions in multiple sclerosis. In patients with multiple sclerosis, the incidence of abnormality of motor and somatosensory evoked potentials was similar. Central motor conduction time was correlated with overall and pyramidal tract subscores on the Kurtzke Disability Status Scale and the Scripps Neurological Rating Scale. Central motor conduction time abnormalities correlated best with the presence of a Babinski's sign but also correlated significantly with weakness and hyperreflexia.

(*Arch Neurol.* 1991;48:944-948)

Magnetic coil (MC) stimulation of the human motor system has received increasing attention in the clinical neurophysiological literature since its introduction by Barker and coworkers[1] in 1985. The advantages of this technique over transcranial electrical stimulation are less patient discomfort, more consistent stimulation of deeper neural structures, and ease of stimulus application.[2] Minor disadvantages are the relative dispersion of the response wave forms, variability of the amplitude of these wave forms with successive stimulation, and the uncertainty of location of the precise point of MC stimulation.[3]

Electrical stimulation of the motor pathways has been used to study multiple sclerosis (MS) in both upper and lower extremities.[4-6] Magnetic coil stimulation techniques have been used to study motor evoked potentials (MEPs) in patients with a variety of neurologic disorders including MS.[7-12] Most of those studies using electrical stimulation focused primarily on the responses obtained from the upper extremities. These studies often included determinations of central motor conduction time (CMCT), but usually in combination with transcutaneous electrical stimulation of the spinal cord and motor roots.[2] Several studies have used MC stimulation to obtain MEPs and to calculate CMCT to the lower extremities.[8,10-12] The purpose of our study was to determine if MC stimulation and MEPs in the lower extremities were clinically useful in patients with definite MS. Our technique differed from that of other investigators in that the entire procedure was performed with the MC and utilized a method of CMCT determination involving M- and F-wave latencies. We examined correlations between MEP parameters and our patients' neurologic signs.

PATIENTS AND METHODS

Patients and Control Subjects

Control subjects consisted of 30 healthy volunteers (19 men and 11 women) with a mean age of 30.5 years (range, 19 to 50 years). The patient group was drawn from the Multiple Sclerosis Center of Thomas Jefferson University Hospital, Philadelphia, Pa, and consisted of 25 hospitalized patients with the diagnosis of definite MS.[13] There were 14 women and 11 men with a mean age of 40.8 years (range, 32 to 52 years).

All subjects gave informed consent to a protocol approved by the Thomas Jefferson University Hospital institutional review board. All patients had neurologic examinations with particular attention to pyramidal tract signs. Motor strength was assessed by the 0 to 5 Medical Research Council scale, and all patients were scored on the Kurtzke Expanded Disability Status Scale[14] and the Scripp's Neurological Rating Scale.[15] In addition to the MEP studies, all patients with MS had lower extremity somatosensory evoked potentials (SEPs) performed according to the American Electroencephalographic Society guidelines.[16] Most underwent magnetic resonance imaging of the brain and spinal cord and cerebrospinal fluid immunoglobulin studies.

MEP Stimulation and Recording Technique

Magnetic coil (Caldwell MES-10) stimulation was accomplished with a 9.5-cm circular coil that generated a 2.2-T sinusoidal pulse at 100% output. The common peroneal nerve was stimulated at the fibular head. The coil was held tangentially with the coil edge positioned over the nerve. The MEPs were recorded using standard electromyograph electrodes with the active lead over the motor point of the anterior tibial muscle and the reference lead over the anterior tibial tendon. The response was recorded with a conventional electromyograph (Teca TD-10) using a cathode ray tube with a sweep of 50 to 100 milliseconds [ms] and a sensitivity of 0.5 to 1.0 mV per division. Transcranial MC stimulation of the motor cortex was obtained with the coil held tangentially to the scalp, 15 cm rostral to the inion. The center was slightly posterolateral to the vertex. The MEPs were first recorded with the foot of the target limb slightly dorsiflexed (5% to 10% maximum contraction), which facilitated the response. This was followed by a second recording at rest. Stimulus intensity was set between 80% and 100% output. If there was any variation in the latency of anterior tibial muscle responses to transcranial, lumbar, or peripheral magnetic stimulation, the shor-

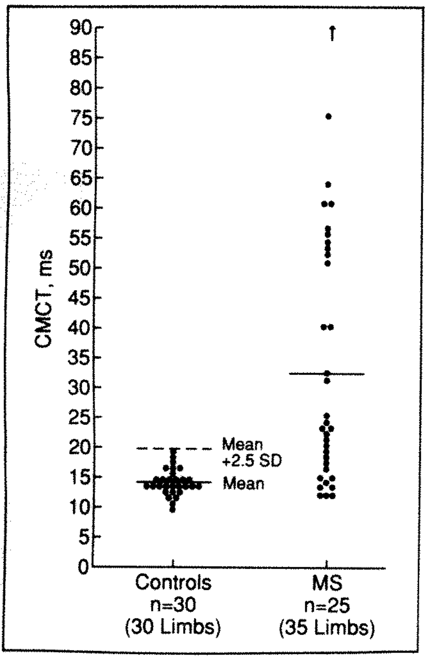

Fig 1.—Scattergram of central motor conduction time (CMCT) in the lower extremities of 30 control subjects (left) and 25 patients with multiple sclerosis (MS) (right). Recordings were made from one limb in the control group and from both limbs in patients with MS. Responses were obtained in 34 of 50 limbs in the latter group. Unobtainable responses were abnormal but are not reflected in the mean (solid line) or the standard deviation (dashed line). Some markedly prolonged values in the MS group are not included on the graph (arrow).

Table 1.—Comparison of Motor Evoked Potential (MEP) and Somatosensory Evoked Potential (SEP) in the Lower Extremities

SEP	25	5	20	0

test measured response was used for data analysis. In all subjects, peroneal nerve stimulation was necessary both to evaluate the integrity of the peripheral nerve and to measure peripheral latencies (M- and F-wave latencies) to the compound muscle action potential in the anterior tibial muscle. The M- and F-wave latencies and the MEP latencies were measured to the nearest 0.1 ms, and the baseline peak amplitude was measured to the nearest 0.1 mV.

The CMCTs were calculated using an indirect method of measuring peripheral contribution to the MEP latency using the formula (F+M-1)/2. This was subtracted from the MEP latency to yield the CMCT. This method for obtaining F-wave latencies with peripheral magnetic stimulation has been described elsewhere.[17-21] Magnetic stimulation was used instead of conventional electrical stimulation because no significant differences were found between the two methods in several normal subjects. Using the MC for both peripheral and cortical stimulation made the procedure less time-consuming to perform and more comfortable for the subjects.

If the F wave was atypical, the latency obtained with direct stimulation of the lumbar roots were used to measure peripheral conduction and to calculate the CMCT to confirm the reliability of the F-wave measurement. This was accomplished with the coil held tangentially at the midline over the L4-5 interspace. The latencies of the recorded responses to lumbar stimulation remained constant, with minor variations in coil position. Lumbar stimulation gave a consistently shorter measure of the peripheral component of the MEP latency than that obtained using F-wave latencies, resulting in a proportionately longer calculated CMCT. These findings were consistent with results from previous work in our laboratory and others.[17,22]

Data Analysis

The criteria for MEP abnormalities in the patient population consisted of the absence of an MEP response at rest or with dorsiflexion, prolongation of the MEP latency, or CMCT greater than 2.5 SD above the mean values derived from the control subjects. The MEP amplitude was not used as a criterion in the evaluation of the patients because of the large intertrial variability of this parameter in previous studies.[8] The SEP abnormalities were assessed using the amplitude and latency criteria established by the American Electroencephalographic Society.[16]

Statistical correlations between MEP and SEP findings and clinical neurologic signs were made using a χ^2 test. The Kurtzke scale subscores for pyramidal function (weakness) and spasticity, and the Scripps subscores for motor strength, deep tendon reflexes, and Babinski's sign, were correlated with CMCT using Spearman's rank correlation coefficients.

RESULTS

Magnetic coil stimulation was well tolerated by both control subjects and patients. No untoward side effects were encountered in patients or volunteers to MC stimulation of the head or limbs. None of the subjects with MS have developed seizures since being stimulated. Reproducible MEPs from the anterior tibial muscle were obtainable in all normal subjects in both the relaxed and facilitated states. Although some investigators report occasional absence of resting MEPs in the lower extremities with MC stimulation, we believe that this is attributable to differences in MC equipment and technique.[10] Other investigators using similar equipment and technique have had similar success.[21] The control group data yielded a mean MEP latency of 30.6 ms (range, 6.7 to 35.2 ms; SD ± 2.2 ms). The mean CMCT measured with F waves had a value of 13.8 ms (range, 9.7 to 18.0 ms; SD ± 1.9 ms). The mean CMCT measured with lumbar stimulation had a value of 16.2 ms (range, 12.6 to 19.3 ms; SD ± 1.7 ms). These measurements showed considerable reliability and stability.[17]

In seven of the 25 patients with MS who were studied, the MEP responses were not obtainable in either limb. In two patients, MEP responses could be obtained in only one limb. In the 18 patients with MS in whom MEPs were recorded, the mean MEP latency was 49.6 ms (SD ± 20.7 ms) at rest, and the mean CMCT was 33.7 ms (SD ± 22.5 ms). Some values were markedly prolonged (Fig 1). For each patient, the resting MEP response was used to calculate the CMCT. Thus, the MEP was abnormal in 21 of the patients with MS (84%) in either one limb (4/25) or both limbs (17/25). Four patients had normal MEPs in both legs. All patients had lower extremity SEPs performed, and these compared favorably ($\chi^2 = 27.1$; $P = .0001$) with the MEP results (Table). Of the 50 limbs evaluated, 34 (68%) demonstrated abnormalities in both MEP and SEP studies. In no patient in whom the MEP was bilaterally normal was a SEP abnormality found. In one limb of a patient with MS, the MEP was abnormal, while the SEP was normal. In four patients (16%), the MEPs and the SEPs were bilaterally normal. In no patients were peripheral motor or sensory conduction abnormalities detected using these methods.

In one patient in whom the diagnosis of MS had not been initially established, an MEP abnormality was detected in the right leg in the absence of weakness, hyperreflexia, or a Babinski's sign. The MEPs obtained from the arms were normal, but the lower extremity SEPs were abnormal and correlated with a sensory disturbance. Subsequently, the visual evoked potentials, cerebrospinal fluid IgG index, oligoclonal bands, and magnetic resonance imaging studies of the brain and spinal cord confirmed the diagnosis of MS (Fig 2). This patient illustrates how this technique may be capable of demonstrating subclinical motor dysfunction.

With regard to the correlation of MEP abnormalities and clinical signs, the MEP parameters of amplitude, latency, and CMCT were assessed. The variability of the amplitudes of the responses, even in normal subjects, made

Figure 2.

Fig 2.—A 34-year-old woman presented with paresthesias of hands and feet. Results of motor, cranial nerve, and cerebellar examinations were normal. Sensory examination revealed decreased vibration sense in the right and left feet. The deep tendon reflexes were brisk and symmetrical with flexor plantar responses. The cerebrospinal fluid had oligoclonal banding (IgG%, 23; IgG index, 1.0). Median nerve somatosensory evoked potentials were normal, but the right posttibial somatosenosory evoked potential showed a delayed P38 component. Top, Motor evoked potentials (MEPs) were performed on upper and lower extremities. Stimulation was applied at the motor cortex (MC) with recording at the abductor policis brevis (APB) and anterior tibial (AT) muscles. Upper extremity MEPs were normal. Lower extremity MEPs were normal on the left and delayed on the right (arrow) with a prolonged central motor conduction time (CMCT). The CMCT was calculated using M- and F-wave latencies obtained in recordings from stimulation at the fibular head (FH). Bottom left, Axial, first-echo, T_2-weighted magnetic resonance image of the brain shows multiple white matter lesions in the parietal and occipital regions with sparing of the cerebral motor pathways. Bottom right, An enhanced T_1-weighted sagittal magnetic resonance image of the thoracic spine demonstrated a high-signal lesion at the T-6 level of the spinal cord (arrow) consistent with an acute multiple sclerosis plaque.

it difficult to correlate amplitude with either CMCT or degree of disability. Others have found this same problem when looking at the lower extremity.[8] Using a χ^2 test, the presence or absence of an MEP abnormality correlated rather poorly with the classic pyramidal tract signs of motor weakness, spasticity, and hyperreflexia. However, with this statistical test, the CMCT slowing correlated significantly with the plantar response ($\chi^2 = 7.6$; $P = .01$).

To compare MEP data (CMCT) with nonparametric ordinal rating scales (Scripps and Kurtzke), we utilized the Spearman rank correlation coefficient. This was optimized by selecting the motor subscores for the lower extremities (Table 2). The Scripps scale yielded significant correlations when the CMCT was compared with motor weakness, deep tendon reflexes, and plantar response. No correlation was found with the Kurtzke subscores. The Kurtzke subscores for pyramidal signs (weakness) and spasticity do not allow for analysis of the legs alone or of the individual extremities. This probably accounts for much of the lack of correlation between these scores and the CMCT. Attempts at simple correlation between global neurologic deficits using either the total Scripps Neurological Rating Scale score or the Kurtzke Extended Disability Status Scale score did not reach statistical significance (Fig 3).

COMMENT

Our observation of a high incidence of MEP abnormalities in MS (84% of patients with definite MS) is similar to the results of lower extremity SEP studies.[23,24] Quantifying the incidence of abnormality is a necessary step in establishing the clinical accessibility of the involved central motor pathways to study using this new electrophysiological technique. The use of MC stimulation for both peripheral and central stimulation is an innovation that we have made in our technique. Although some controversy exists regarding the clinical applicability of MC stimulation of peripheral nerves in routine electromyographic studies,[25,26] in our laboratory no significant differences have been observed between magnetic and electrical stimulation of peripheral nerves for purposes of determining the latency of M or F waves. Also, the F-wave technique gives a consistently shorter and more accurate measurement of CMCT than does lumbar stimulation. This is because in lumbar stimulation the nerve roots are stimulated; therefore, conduction through the more proximal roots to the alpha motoneurons is not part of the measurement of peripheral conduction times.[17,20-22] Additionally, this technique afforded ease of recording and less patient discomfort than did conventional electrical stimulation.

Our incidence of MEP abnormalities is slightly higher than that found in previous MS studies in which the responses obtained in distal muscles of the upper extremities were examined. We believe that this may be attributable to several factors. The parasagittal location of the leg on the mesial frontal motor cortex makes it less accessible to MC stimulation. Additionally, the number of pyramidal tract fibers reaching the lumbosacral segments of the spinal cord is relatively small compared with the cervical region supplying arm muscles.[27,28] These anatomical facts may have resulted in a higher percentage of absent responses. However, the most likely reason for the increased percentage of abnormalities is that by recording from the lower extremity the efferent motor volley must traverse a longer pathway through the brain and spinal cord. Therefore, it is more likely to encounter a demyelinated region, resulting in an abnormal MEP. Small demyelinating lesions in the pyramidal tract have been suspected to be a frequent early clinical sign of MS.[29,30]

Table 2.—Correlation of Neurologic Scales and Central Motor Conduction Time*

Pyramidal Tract Signs	Scripps Score	Kurtzke Score
Motor weakness	$P = .05$	NS
Spasticity	. . .	NS
Deep tendon reflexes	$P = .05$	. . .
Plantar response	$P = .05$	. . .

*NS indicates not significant.

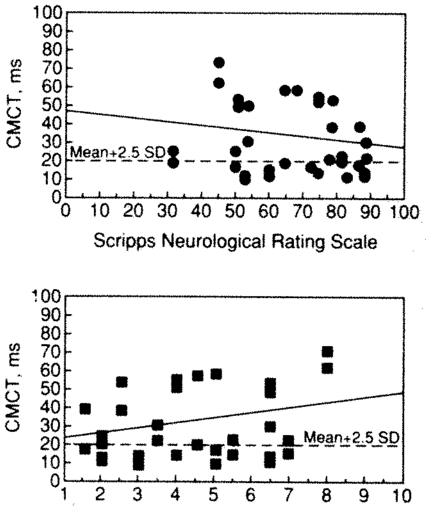

Fig 3.—Linear regression graphs comparing values for central motor conduction times (CMCTs) with the overall scores for the Scripps (upper graph) and Kurtzke scales (lower graph) for rating the neurologic examination in patients with multiple sclerosis. Note that a lower Scripps score and a higher Kurtzke score indicate greater disability. Some normal CMCT values were found in patients with Scripps and Kurtzke scores reflecting severe disability. This happened in cases in which the disability was caused by nonpyramidal lesions. The regression lines show a definite trend; however, these did not reach statistical significance. The dashed line shows the upper range of normal (mean + 2.5 SD) for CMCT from the control data.

The typical MEP abnormalities that we found were the same as those found by others who studied the upper extremities, ie, prolongation of latency or an absent response.[3,6-12] The delay in the CMCT measurements of our patients with MS is entirely consistent with the type and degree of electrophysiological abnormality in MS, ie, central demyelination. This probably arises as a result of conduction block of the corticospinal fibers, selective fiber loss in this pathway with utilization of other multisynaptic motor pathways, or the failure of high-frequency conduction responsible for the temporal summation of excitory postsynaptic potentials at the level of the lumbar spinal motoneuron.[31] The abnormalities of the MEP in the lower extremities of patients is not specific to MS or to demyelinating disease. In our laboratory and others, similar abnormalities have been revealed by MEPs in patients with cerebral and spinal cord dysfunction of other cause, including stroke, trauma, and degenerative disorders.[6,10,32,33]

The correlations between the clinical signs and neurologic rating scales need clarification. Like other evoked potential studies, MEPs are capable of demonstrating subclinical lesions of the brain and spinal cord. The presence of MEP-detected but clinically silent lesions and severe disability secondary to nonpyramidal tract lesions, ie, coordination, vision, and bowel or bladder involvement, reduced correlation between the CMCT and the overall Scripps and Kurtzke scores. This latter problem was eliminated by using the Scripps and Kurtzke subscores for signs reflecting only the involvement of the pyramidal tract. The Scripps scale showed certain advantages over the Kurtzke scale in that individual lower extremity ratings could be subscored to yield better correlation. It is notable that among the classic pyramidal tract signs, the Babinski sign correlated best with MEP abnormalities. Nevertheless, motor weakness and hyperreflexia correlated with CMCT when the individual lower extremities were considered separately. These observations suggest that quantitative assessment of motor deficits may be obtained in patients with MS. This may overcome some of the shortcomings of the more global neurologic rating scales and measurements of motor strength.[34] Measurements obtained in transcranial MC stimulations and MEPs may provide data that are more amenable to statistical analysis with which to determine clinical changes in the course of disease or following therapy.[35,36]

In summary, MEP abnormalities may be found with a high incidence in patients with definite MS. These abnormalities include absence and delays of the MEP and prolongation of the CMCT. These may occur in the absence of clinical signs of motor dysfunction. The MEP abnormalities correlated with the SEP abnormalities in the legs. The CMCT abnormalities clinically correlated best with pyramidal tract signs. Global neurologic rating scales also show a trend toward correlating with MEP abnormality in the more neurologically disabled patients with MS. Thus, MEPs in the lower extremity appear to be a valuable procedure in the diagnosis and evaluation of motor deficits in patients with MS. Studies of patients with MS who lack clinical signs of motor involvement will determine whether MEPs in the lower extremities will be as useful as other evoked potentials in detecting subclinical effects of demyelination in the central nervous system.

This study was supported, in part, by awards from the National Institute of Disability and Rehabilitation Research to the Regional Spinal Cord Injury Center of Delaware Valley (G008535135) and the National Rehabilitation Research and Training Center in Spinal Cord Injury (H133B80017), Thomas Jefferson University Hospital, Philadelphia, Pa.

We appreciate the technical support of Ming Hwang, REEG/EPT and Sabrina B. Beacham, REEG/EPT and the secretarial assistance of Lois Tolbert in the preparation of this manuscript.

Frontal Verbal Amnesia

Phonological Amnesia

H. Branch Coslett, MD; Dawn Bowers, PhD; Mieke Verfaellie, PhD; Kenneth M. Heilman, MD

• Although aphasic patients with frontal lobe damage may demonstrate impaired retention of verbal material, significant anterograde memory disturbances have not, to our knowledge, been reported with a minor Broca's aphasia. We describe a patient with minor Broca's aphasia who exhibited an unusual and profound anterograde memory disturbance, especially for phonologically specified stimuli. We suggest that this disturbance is attributable to an impairment in the volitional, controlled search of stored phonological information.

(*Arch Neurol.* 1991;48:949-955)

A number of investigators have demonstrated that anterior aphasia may be associated with impaired retention of verbal material.[1-3] Cermak and Moreines,[4] for example, reported that patients with nonfluent aphasia were impaired on a phonological memory task involving the detection of rhymes; they proposed that anterior aphasia induced a defect of "phonemic recirculation." More recently, Cermak and coworkers[5] have further suggested that the memory deficits of anterior aphasics may be related to an inability to compare phonological items already in memory and difficulty in "reconstructing" items based on phonological features.

Broca's aphasia is typically associated with lesions involving Broca's area as well as portions of the anterior perisylvian region, including the sensory motor cortex, insula, and anterior parietal operculum.[6] Smaller lesions largely or entirely restricted to Broca's area, however, have also been shown to be associated with a language disturbance; this syndrome, designated *minor Broca's aphasia* by Foix,[7] is characterized by a combination of difficulties, often including word-finding disturbance, effortful articulation, and decreased verbal fluency. Although sometimes initially severe, these symptoms are typically transient, and persistent, overt language disturbances are uncommon.

Although nonaphasic patients with left frontal lobe lesions may have lexical retrieval impairments, as evidenced by their poor performance on controlled word association tasks,[8,9] to our knowledge significant anterograde memory disturbances have not been reported with a minor Broca's aphasia. We describe a patient with minor Broca's aphasia subsequent to an ischemic infarction involving Broca's area and small portions of the inferior and middle frontal gyri who exhibited an unusual and profound anterograde memory disturbance; we suggest that this disturbance is attributable to an impairment in the volitional, controlled search of stored phonological information.

REPORT OF A CASE

The patient was a right-handed 59-year-old man who was admitted for evaluation of a memory impairment. He had been in excellent health until 3 years prior to admission when, 1 week after a transient episode of left-eye blindness, he noted the sudden onset of difficulty in speaking and weakness of the right side of his body. Neurologic evaluation at that time revealed a mild right hemiparesis, a nonfluent aphasia with mildly impaired auditory comprehension, and a Gerstmann's syndrome. The auditory comprehension impairment and Gerstmann's syndrome resolved within several days. Unfortunately, no additional information about the patient's initial language impairment is available.

Although family members noted no impairment in his speech after the stroke, the patient considered himself to be appreciably less articulate because he had difficulty in finding the appropriate word and in "getting words out."

In the estimation of the patient and his family, however, his subtle speech impairment paled in significance relative to the severe and disabling memory deficit noted subsequent to his stroke. Although he believed his memory for faces, pictures, and places to be relatively unimpaired, he stated that his memory for names and verbal material, whether written or spoken, was quite poor. As a consequence of his memory deficit, he was unable to return to his job as a loan officer for a finance company; he worked briefly as a prison officer before his memory disturbance forced him to retire.

Neurologic examination 3 years after the stroke revealed a mild spastic weakness and clumsiness of the right hand. Evaluation of the patient's higher nervous system functions revealed that his spontaneous speech, although marked by occasional word-finding pauses, was fluent, with normal prosody and articulation. His discourse contained a normal range of syntactic structures. Naming, although occasionally hesitant, was normal. Repetition of words, phrases, and sentences was excellent; sentences of up to 12 words, as well as sentences with unusual syntactic structures, such as center-embedded clauses, were repeated perfectly. Auditory comprehension was unimpaired. The patient read aloud and for comprehension quite well. No effect of orthographic regularity, part of speech, or imagery was noted in his reading. His writing was normal. Calculations, right-left discrimination, and finger naming were normal. No buccofacial or limb apraxia was noted. There was no neglect. He was able to draw a cube, as well as maps of the United States.

A computed tomographic scan performed 3 years after the patient's stroke revealed an old area of infarction involving Broca's areas, as well as more rostral portions of the inferior frontal gyrus. Additionally, small portions of the precentral and middle frontal gyri were also infarcted (Figs 1 and 2).

NEUROPSYCHOLOGICAL EVALUATION

Intellectual

On the Weschler Adult Intelligence Scale, the patient obtained a verbal intelligence quotient (IQ) of 93, a performance IQ of 88, and a full-scale IQ of 91. His performance IQ was thought to have been adversely influenced by his right-hand clumsiness. The Peabody Picture Vocabulary Test[10] yielded a verbal IQ estimate of 103.

Language

A number of formal tests were administered for more careful assessment of the patient's language capacities. His performance on the Western Aphasia Battery[11] and selected portions of the Boston Diagnostic Aphasia Examination,[12] including the reading, repetition, and writing subtests, was essentially perfect. For further assessment of the patient's auditory comprehension, the Token Test[13] was administered; the patient made one mistake on subtest VI, but otherwise his performance was perfect. He performed normally on the Boston Naming Test[14]; the Florida Syntax Comprehension Test,[15] in which correct performance is critically dependent on comprehesion of the distinction between indirect and direct objects; and the Battery of Adult Reading Function,[16] a test that assesses reading comprehension and the reading aloud of reg-

ular and irregular nouns, functors, and nonwords. The Story Completion Test[17] was also administered; with a single exception, the patient generated a response of the desired syntactic form.

Frontal Lobe Tasks

Several cognitive tasks sensitive to frontal lobe functioning were administered. The patient performed poorly on the Wisconsin Card Sorting Test[18]; he failed to detect the correct sorting principle after 35 trials. Approximately 20% of his errors were random guesses and 50% were perseverative errors. The patient was also impaired on the color-naming and interference subtests of the Stroop Interference Task.[19] He required 88 seconds to name color patches (1.5 SDs below the mean) and 288 seconds to complete the interference task (2 SDs below the mean). The patient demonstrated no perseveration in Luria's "mn" writing task but performed quite poorly on the "go–no go" and contrasting motor programs task.[20]

Attention and Memory

Digit span was assessed on a number of occasions. The patient correctly repeated 100% of orally presented five-digit lists and 60% of six-digit strings. Seventy-one percent of the errors were sequencing errors, and 29% of the errors were due to the omission of a single item. With visual presentation of single-digit written numbers at the rate of approximately one number per second, the patient's performance was quite similar. Administration of the Wechsler Memory Scale[21] revealed the patient to have a memory quotient of 71 (Table 1). His story recall of the logical memory stories from the Wechsler Memory Scale was six initially (average normal, 10) and four after a 20-minute delay (average normal, eight). His paired-associate learning was similarly impaired on word-list learning tasks, both with auditory and visual presentation. On the Rey Auditory Verbal Learning Test,[22] for example, he recalled no more than six of the 15 words across any of five learning trials, and his delayed 20-minute recall was three. Similar results were obtained with visual presentation. His memory performance fell more than 2 SDs below the mean of age-matched controls.

The patient's performance on the Rey Auditory Verbal Learning Test also provided an opportunity for assessment of the effects of recency and primacy in supraspan list learning. On the first five trials on both the auditory and visual versions of the Rey Auditory Verbal Learning Test, the patient correctly produced 90% of the 20 items presented in the last two positions. Additionally, the effects of recency and primacy were evaluated by calculation of the percentage of words reported as a function of position in the list; in the first five trials on the auditory and visual versions of the test, the patient correctly reported 20% of the words from the first third, 16% of the words from the middle third, and 72% of the words from the last third of the list. Thus, the patient exhibited a clear effect of recency but no clear effect of primacy.

In contrast, the patient performed much better on nonverbal recent memory tasks such as the Milner Facial Recognition Test[23] and Kimura's Recurring Figures Test.[24] He correctly identified nine of the 12 target faces and obtained a score of 44 on the latter task; his performance was in the normal range on both tasks.

Table 1.—Wechsler Memory Scale (Form I)

Information	6
Orientation	5
Mental control	6
Memory passages	6, 4 delayed
Digits total	8
Visual reproduction	5
Associate learning	1.5
Memory quotient	71

Thus, the patient performed normally on a wide range of language tasks and exhibited a normal verbal IQ. In spite of his at least relatively normal language skills, however, he has a marked verbal memory deficit with sparing of nonverbal memory. The following investigations were performed to further characterize the patient's memory impairment.

Rate of Forgetting.—As performance on tests assessing the rate of forgetting has been demonstrated to distinguish between amnestic syndromes caused by bitemporal vs diencephalic damage,[25-27] the patient's rate of forgetting was assessed in a manner similar to that described by Huppert and Piercy.[25] One hundred target stimuli (pictures) were individually projected on a screen for a period of 8 seconds each. At intervals of 10 minutes, 20 minutes, 90 minutes, 24 hours, and 1 week after this presentation, different random subsets of 20 pictures from the original sample and 20 new pictures were projected, and the patient was asked to indicate whether each picture was from the original list of stimuli. Five age- and education-matched controls were tested in a similar fashion, except that stimuli were presented for 1 second each. Although the difference in exposure times renders a comparison with control subjects difficult, it is apparent from examination of Fig 3 that the patient's performance was quite similar to that of five age- and education-matched controls, falling within 1 SD of their performance at every test interval.

The patient's rate of forgetting for verbal stimuli was also assessed in the manner described above. Stimuli for this experiment included 100 slides depicting a single typed word. The target words were presented for 8 seconds each, and the patient's recognition was assessed in the manner described above. The patient correctly sorted only 57% of the stimuli at both 10 and 20 minutes; as his performance was not above the chance level ($\chi^2 = 1.63$; $P > .1$), this investigation was discontinued after the second session. Errors included an almost equal number of false-positives and false-negatives. With a 1-second stimulus exposure, controls correctly identified 81% and 75% of stimuli at 10 and 20 minutes, respectively, and remained well above chance (67% correct) after 1 week (Fig 4).

Thus, the patient's rate of forgetting was essentially normal for "nonverbal" material; his rate of forgetting for verbal material could not be assessed, as we could not demonstrate evidence of adequate initial performance.

Effect of Interference.—A Peterson and Peterson[28] task adapted from Butters and Grady[29] was given to assess the effects of interference on the patient's verbal memory performance. On each trial, three semantically and phonologically unrelated monosyllabic or bisyllabic words were auditorally presented to the patient at the rate of approximately one word per second. Five trials were presented in each of four conditions: (1) immediate recall, in which there was no delay between stimulus presentation and production; (2) a 20-second unfilled delay between stimulus presentation and production, during which the patient was permitted to rehearse; (3) a 20-second filled delay, during which the patient was asked to count backward by twos before recalling the stimuli; and (4) a 4-second unfilled interval, during which the patient was encouraged to rehearse, followed by a 16-second period, during which the patient was asked to count backward by twos. In the immediate recall and 20-second unfilled delay conditions, the patient correctly produced all 15 of the target words; with a 20-second filled delay, the patient produced only two (13%) of 15 words; with a 4-second predistractor delay, followed by a 16-second filled delay, he produced nine (60%) of 15 words (Fig 5). On the latter two conditions, errors included 16 omissions and two intrusions. No semantic errors were noted. The patient's performance was quite similar with visual presentation of the stimuli. He made no errors in the immediate recall and unfilled delay conditions, and he correctly produced six (40%) of 15 stimuli with a 20-second filled delay and produced eight (53%) of 15 stimuli with a 4-second predistractor period and a 16-second delay and distraction. Errors included three intrusions and 13 omissions.

These data suggest that the patient is quite sensitive to the effects of interference or, alternatively expressed, dependent on continued rehearsal. In conjunction with the demonstration that the patient exhibited a relatively normal recency effect, these data suggest that rehearsal within the articulatory

loop is not impaired.

Release from Proactive Inhibition.—In an attempt to assess the possible role of impaired semantic/conceptual encoding in the production of the patient's memory deficit, a release-from-proactive-inhibition task similar to that of Cermak et al[3] was administered. This task was derived from Wickens'[30] modification of the Peterson and Peterson[28] distraction technique, in which subjects were given several consecutive trials of word stimuli, all of which belonged to the same semantic category (eg, fruits). This was followed by a trial in which the word stimuli were exemplars of a different category (eg, vegetables). As previously documented, memory performance in normal subjects deteriorates over trials, because of the buildup of proactive interference. Wickens[30] demonstrated, however, a dramatic improvement in memory performance on trials when the stimuli came from a different semantic category. This improvement presumably stemmed from a release of proactive interference that occurred because subjects had noted the change or shift in the semantic category of the stimulus words. The underlying assumption is that stimuli must be semantically encoded for the release effect to occur.

To assess release from proactive interference, the patient and controls were tested on a Peterson and Peterson[28] distraction task involving eight blocks of five trials. Stimuli for each trial consisted of three semantically related concrete nouns (eg, pear, apple, and grape) read aloud to the patient. After a 20-second delay filled with counting backward by twos, the patient was asked to produce the three target words. There were two conditions. In the *no-shift condition*, all five trials of the block consisted of word stimuli from the same semantic category (eg, fruit). In the *category shift condition*, word stimuli on trial 5 were from a different semantic category (eg, vegetables) than the preceding four trials of the block. Category shift and no-shift conditions were randomized, with 5-minute rest intervals between each block. The performance of the patient and normal controls across trials 1 through 5 of the categoryshift and no-shift conditions is shown in Fig 6. For both the patient and the controls, there was a progressive decline in performance across trials 1 through 4 of both conditions, with the patient exhibiting a greater decrement, which presumably reflects a greater susceptibility to interference. The patient, like amnesic patients with Korsakoff's psychosis,[3] exhibited no "release" effect. For controls, in contrast, the change in semantic class on trial 5 of the category shift condition was associated with a significant increase in recall as compared with the no-shift condition ($\chi^2=4.91$; $df=1$; $P<.05$).

The interpretation of this finding, however, is unclear. Some investigators[3] have argued that the finding indicates that the patients were not encoding in semantic categories. Alternatively, on the basis of a comparison of the performance of patients with frontal or temporal lobectomy on a release-from-proactive-inhibition task, Moscovitch[31] has argued that the phenomenon is more appropriately associated with frontal impairment than with memory loss.[32] Because our patient was impaired on tests of frontal lobe function as well as memory, the explanation for his failure to manifest the release phenomenon is not clear.

Memory for Phonology.—Levels of Processing.—Perhaps the most striking aspect of the patient's verbal memory deficit was a marked discrepancy between performance on tasks requiring registration and/or retrieval of phonologically, compared with semantically, specified items. This phenomenon was first noted on a task employing the "levels of processing" paradigm.[33] This experiment was motivated by a conceptual framework suggesting that the adequacy of memory registration is a function of the depth of analysis or the degree to which the stimulus is semantically processed.

Stimuli for this task included 36 target words printed on a 4 × 6-in card; half of the words were printed in uppercase and half in lowercase letters. Stimuli were shown to the patient for approximately 5 seconds each; immediately after the presentation of each stimulus, the patient was asked one of three types of orienting questions: (1) one third of the stimuli were accompanied by orthographic orienting questions (eg, "Is this word written in uppercase letters?"); (2) one third were accompanied by phonological orienting questions (eg, "Does this word rhyme with fear?"); and (3) one third were accompanied by semantic orienting questions (eg, "Is this a type of fruit?"). Ten minutes later, a recognition memory task was administered in which thirty-six 4 × 6-in cards, each containing one of the stimuli and three phonologically and semantically unrelated foils, were presented. The patient was asked to indicate which of the four words had been previously presented.

As depicted in Fig 7, the patient correctly identified 87% of the words introduced with a semantic orienting question, 87% of the words introduced with an orthographic orienting question, but only 25% of the words introduced with a phonological orienting question. In contrast, five age- and education-matched controls showed the expected pattern, correctly identifying 91% of the semantically, 75% of the phonologically, and 67% of the orthographically cued words.

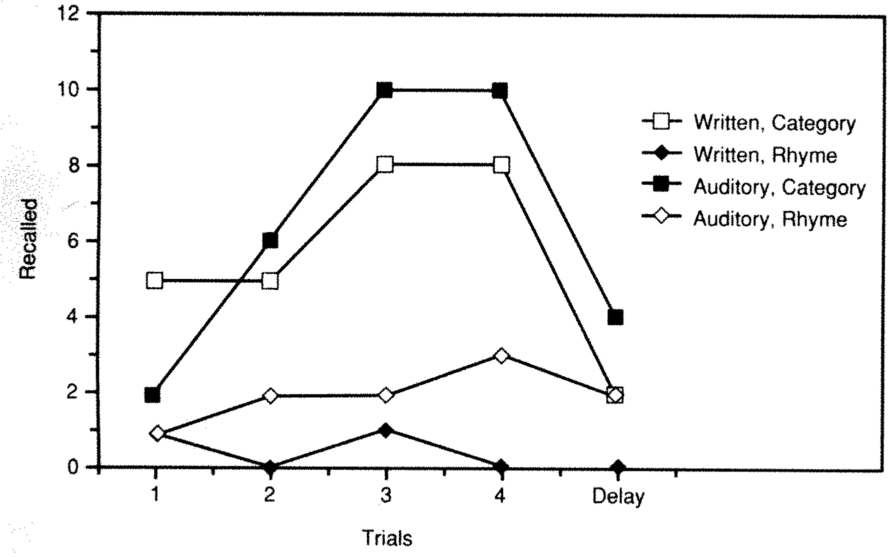

Fig 8.—Number of rhyming and semantically related paired associates recalled by the patient with auditory and written stimuli.

Table 2.—Fluency Tasks

	Patient	Controls
Letters		
f	2.4	. . .
a	2.0	. . .
s	2.6	. . .
Semantic categories	12.3	14.5
Rhyming words	2.0	8.4
Nonverbal (figures)	16.0	. . .

The patient's selective memory deficit for phonologically cued stimuli could not be attributed to an inability to make rhyme judgments, in that he was 100% accurate when answering rhyme orienting questions.

An auditory version of the levels of processing task was also performed. On this task, the orthographic orienting question was eliminated, and the patient was asked to indicate if the words were spoken in a male or female voice. The patient correctly identified 93% of the words presented with a semantic orienting question, 75% of the words introduced with a male/female voice orienting question, but only 25% of the words introduced with a phonological orienting question. Controls correctly identified 91%, 75%, and 67% of stimuli introduced with semantic, phonological, and voice orienting questions.

Rhyming Paired-Associate Tasks.—The patient's apparent deficit in memory for phonologically encoded and/or retrieved information was also assessed using two list-learning tasks adapted from Warrington and Weiskranz.[34] Stimuli for one task included 12 pairs of semantically related words (eg, "ask" and "inquire"); stimuli for the second task included 12 pairs of rhyming words (eg, "chair" and "bear"). The word pairs from each list were read to the patient at the rate of one word per second. After presentation of the paired-associate list, the patient was given the first word of the pair and asked to produce its associate. This procedure was repeated for a total of four trials for each of the two lists. Delayed recall of the word pairs was tested after a 30-minute delay. The semantically and phonologically related word pairs were presented in different sessions. Both visual and auditory versions of these lists were given.

The patient's performance with written and auditory stimuli presentation is presented in Fig 8. He performed better with semantically related stimuli on each trial with both written and auditory stimuli. With written stimuli, this difference reached significance on trials 2, 3, and 4 ($\chi^2=6.3$, 8.7, 12.0, respectively; all $P<.01$). With auditory stimuli, he performed significantly better with semantically related pairs on trials 3 and 4 ($\chi^2=10.7$and 8.2, respectively; both $P<.05$). Summing across the five trials, the patient performed significantly better with semantic, as compared with rhyming, paired associates with both written ($\chi^2=30.0$; $P<.01$) and auditory ($\chi^2=17.7$; $P<.01$) stimuli. Age- and education-matched controls demonstrated no significant difference between rhyming and semantically associated words on individual trials but did demonstrate a slight but consistent superiority with semantic paired associates which, summing over all five trials, was significant ($\chi^2=5.6$; $P<.05$).

Fluency Tasks.—The effect of phonological factors on retrieval of information from remote or long-term memory was assessed by a number of variants of the Thurstone Word Fluency Test[35] (Table 2). In one investigation, the patient's ability to generate words beginning with a designated letter was compared with his ability to generate words defined on the basis of semantic attributes. In the former task, the patient was instructed to generate in 1 minute as many words as possible that begin with the letter *f*; similar 1-minute trials were performed in which he was asked to generate words beginning with *a* and *s*. Data were collected for each of the three letters during five separate sessions. The patient was also instructed to generate in 1 minute as many exemplars as possible of a specified semantic category. Eight semantic categories were tested on each of two occasions.

As indicated in Table 2, the patient's average score for the letters *f*, *a*, and *s* was 2.4, 2.0, and 2.6 words per minute, respectively; thus, his average across all three letters was 2.3 words per minute. Performance with semantically defined categories was substantially better, as he generated an average of 12.3 items per minute, with a range of 6 to 18.

On another occasion, a word was provided, and the patient was asked to generate as many rhyming words as possible in 1 minute. A total of five words were presented. He produced an average of 2.0 rhyming words per minute; he did not produce nonrhyming words. Age- and education-matched controls, in contrast, generated an average of 8.4 words per minute.

In an effort to demonstrate that the diminished fluency reflected a specifically verbal impairment, a nonverbal analog of the Thurstone Word Fluency Test was administered in which the patient was asked to create as many different drawings in 4 minutes as possible using only four lines.[36] On two trials he created an average of 16 drawings, a performance that is within the normal range.

COMMENT

We have presented data derived from a 59-year-old man with a minor Broca's aphasia secondary to a documented left dorsolateral frontal lobe infarct who demonstrated a severe memory impairment of a type not previously described, to our knowledge. Evaluation of the patient's memory revealed that he was sensitive to distraction, did not demonstrate the normal release from proactive inhibition, showed an effect of recency but not primacy, and, perhaps most interestingly, exhibited a marked memory impairment for the encoding and/or retrieval of phonologically, compared with semantically, specified items. Several issues concerning this patient's performance warrant attention.

The first issue concerns the relationship between the patient's language capacities and his memory impairment. Abundant evidence suggests that both fluent and nonfluent aphasias may be associated with a verbal memory impairment. Might the patient's memory deficit be secondary to a subtle language deficit?

A number of specific mechanisms have been proposed to account for the impairments of short-term memory encountered in aphasic patients. The impaired verbal short-term memory encountered in a probable Wernicke aphasic, for example, has been attributed to a failure to generate an adequate phonological representation[37]; the impairment seen in certain conduction aphasics has been attributed to a pathologic reduction in the capacity of the short-term store[38,39]; finally, in certain Broca's aphasics, the impairment of short-term memory has been attributed to failure of repetition, with a resultant failure of rehearsal in the putative articulatory loop.[15,40]

None of these proposed explanations, however, can account for the data derived from our patient. Our patient exhibited no demonstrable phonological impairment on tests of auditory comprehension, phoneme discrimination, and rhyme judgment. Additionally, our patient had no impairment of repetition and, as indicated by his perfect performance on the Peterson and Peterson[28] task with an unfilled delay, was able to retain phonologically encoded data, presumably by means of rehearsal within the articulatory loop.

Because the patient's infarct involves Broca's area, a brain region thought to be important in the control of motor aspects of speech production, one might suggest that the memory deficit reflects an impairment at the level of motor programming for speech. There are several lines of evidence that make this possibility seem unlikely. The patient's spontaneous speech demonstrates only a minimal abnormality—occasional word-finding problems—that might be attributed to an impairment of the motor programmer. Additionally, this hypothesis provides no principled account of the dissociation between the retrieval of phonologically, compared with semantically, guided retrieval. Finally, a deficit with phonologically cued stimuli was documented on the levels of processing task in which no verbal output was necessary.

A second issue concerns the marked dissociation between the patient's normal phonological processing in naturalistic, "automatic" language tasks such as spontaneous speech, reading, and naming and his marked impairment on memory and fluency tasks requiring the strategically guided, "controlled" retrieval of phonologically specified items. Following Schneider and Shiffrin[41] and Shiffrin and Schneider[42], a controlled process refers to an attention-requiring procedure that may be accessed or developed for the completion of a novel or unusual task. Tasks such as the production of lists of rhyming words that are not part of normal language routines may require a strategically guided or controlled search of lexical phonology. An automatic process, in contrast, is effortless and proceeds without active control; the semantically guided activation of lexical phonology that is thought to characterize normal routines involved in speech production[43] and object naming may involve an automatic process.

Within this framework, one possible explanation for the patient's deficits is an impairment in the controlled search of stored information. This hypothesis may take at least two forms. First, one might propose that the deficit is specific to the domain of lexical phonology; in this hypothesis, the controlled search of lexical semantics is assumed to be normal. Because tasks such as the retrieval of phonology on the basis of rhyme or initial letter are assumed to require controlled search of phonological information, whereas spontaneous speech, naming repetition, and reading are assumed to be mediated by the relatively automatic procedures involved in normal speech production, this hypothesis can account for the patient's performance.

A second explanation is that the patient suffers from a general impairment in controlled search. On this hypothesis, the difference in performance between phonologically and semantically specified items might reflect differences in the amount of effort required for controlled searches of the semantic and phonological stores, which, in turn, may reflect discrepancies in the organization of these stores; an impaired procedure for controlled search may be more effective operating within the semantic domain, in which related items may be "linked," compared with phonological stores, in which such interrelationships are weak or absent. One might expect, for example, that the retrieval of animal names would be facilitated by the multiplicity of semantic and, perhaps, visual attributes that they share; in contrast, preexisting linkages between words sharing an initial letter in the phonological lexicon would be expected to be weak.

The hypothesis that the patient's symptoms reflect an impairment in controlled search of stored information also accounts for another interesting aspect of his performance: the relatively normal recency effect, but the failure to demonstrate primacy. Recency effects are typically attributed to the maintenance of phonological information in the articulatory loop or phonemic buffer; primacy effects, in contrast, are typically attributed to the activation of lexical information. Thus, the ability to produce words from the beginning of a list (ie, primacy) may require the controlled search of lexical phonology, which, in our hypothesis, is assumed to be impaired.

Anatomic studies in monkeys provide data consistent with the proposal that the patient's dorsolateral frontal lobe infarct is associated with a defect in the controlled search of lexical phonology. Chavis and Pandya,[44] for example, demonstrated that the frontal lobes (including the dorsolateral, medial, and orbitofrontal portions) have reciprocal connections with the primary auditory and auditory association cortex. One might speculate that the left dorsolateral frontal lobe plays a critical role in the retrieval of lexical phonology by virtue of its role in the activation of the auditory association cortex (including Wernicke's area), which may support lexical phonology in man.

An important, but thus far unanswered, question is whether the putative deficit in controlled search underlies the patient's memory impairment. Although one might expect a general deficit in controlled search of stored information to cause a memory impairment, in the absence of an explicit account of the role of phonological factors in encoding and retrieval, it is not clear whether a specific impairment in the retrieval of phonologically specified information would cause amnesia. It is also possible, of course, that the impairment in controlled search and memory deficit are unrelated but co-occur because both processes are dependent on structures in the left dorsolateral frontal lobe.

An additional issue concerns the implications of our patient's performance for conceptions regarding the relationship between the frontal lobe and memory. Investigations involving monkeys[45,46] and man[47,48] have suggested that frontal lobe damage may be associated with specific memory impairments. Other researchers, however, have argued that the apparent memory failure observed with frontal lobe damage does not represent a specific impairment of encoding or retrieval but a disruption of more complex forms of human behavior.[9,29] Luria,[49] for example, argued that patients with frontal lobe damage are unable to maintain a stable intention to remember and are plagued by "pathologic inertia" and "high distractibility." In a similar vein, Warrington and Weiskranz[34] proposed that the frontal lobes play a critical role in the cognitive mediation mechanism, which serves to organize, manipulate, and embellish memory input. Signoret and Lhermitte[50] provided empirical support for the proposal that memory deficits associated with frontal lobe damage may be related to a deficit in the organization of material to be learned, rather than encoding or retrieval per se; these investigators described two patients with frontal lobe damage who were severely impaired in paired associate list learning but were relatively unimpaired when the stimuli were presented in a sentence context or with instructions to generate a visual image of the named objects.

Although the data derived our patient confirm previous observations that even relatively minor frontal lobe damage may be associated with a profound memory impairment, these data do not permit one to adjudicate between these possibilities. To the extent that the memory impairment is attributable to the putative deficit in controlled search of lexical phonology, the data support the thesis that frontal lobe amnesia is attributable to higher-level impairments rather than to impaired encoding or retrieval. Alternatively, if the memory deficit and impairment in controlled search are unrelated, the data may be consistent with the view that the frontal lobes are critical for encoding and/or retrieval.

Finally, one might wonder why the at least relatively selective impairment in processing of phonologically cued information demonstrated by our patient has not been reported previously. One possibility is that the impairment has been confounded by the frequent association of dorsolateral frontal lobe lesions with nonfluent aphasia; impairments in the motor aspects of speech production or lexical phonology, which are often observed in association with left dorsolateral frontal lobe infarcts, might obscure the effects of impairment in controlled search.

This study was supported, in part, by the Medical Research Service of the Department of Veterans Affairs and the Memory Disorders Clinic of the Division of Aging, Department of Health and Rehabilitative Services of the State of Florida, Gainesville.

Rapid Recovery From Cortical Visual Impairment Following Correction of Prolonged Shunt Malfunction in Congenital Hydrocephalus

Mary B. Connolly, MB, MRCPI, MRCP(UK); James E. Jan, MD, FRCPC; Douglas D. Cochrane, MD, FRCSC

• Three children with congenital hydrocephalus are described in whom increased intracranial pressure was associated with severe, long-lasting cortical visual impairment. Following shunt revisions or reconstructive craniotomies, visual improvement began within hours. It is speculated that increased intracranial pressure can occasionally result in chronic hypoperfusion of the parietal-occipital lobes, either due to posterior cerebral artery compromise secondary to transtentorial pressure gradient or to direct compression of cerebral tissues.

(*Arch Neurol.* 1991;48:956-957)

Increased intracranial pressure (ICP) caused by shunt malfunction in the treatment of hydrocephalus can occasionally damage the visual pathways.[1] Various mechanisms have been suggested to explain the visual loss. Anterior visual pathway injury can occur from ischemia secondary to papilloedema[2] or from a markedly dilated third ventricle, which presses on the chiasm[3]; and it is also possible for the optic tracts to be compressed by the tentorial edge during herniation of the hippocampus.[4] Damage to the striate cortex and/or optic radiation can cause cortical visual impairment. This is much more likely to be transient than permanent in children who have experienced shunt failures,[5,6] but the recovery of vision tends to be slow, sometimes over a period of 3 to 5 years. In shunt failure the most common mechanism of permanent visual impairment is infarction of the occipital lobes resulting from occlusion of the posterior cerebral arteries during tentorial herniation,[1] but even in these children some degree of visual recovery is common.

We describe three children with congenital hydrocephalus in whom increased ICP was associated with severe, prolonged cortical visual impairment. However, improvement in vision began within hours following the shunt revision. Since 1984, we have studied more than 200 children with severe cortical visual impairment[1,7-9] who were referred to our visually impaired program. This type of quick improvement from prolonged visual loss related to increased ICP, although not complete recovery, in two of the children is most unusual and we have not seen it described in the literature. The possible pathophysiology is described.

REPORT OF CASES

CASE 1.—A female infant was born at 39 weeks' gestation with a thoracolumbar meningomyelocele after a normal pregnancy. Computed tomographic scan showed Chiari II malformation with markedly dilated ventricles. The spinal defect was closed and a ventriculoperitoneal shunt was inserted in the neonatal period. At 2.5 months the shunt was revised because of malfunction. The infant was noted to have been blind since birth, although the full eye examination was normal. She was totally oblivious to her environment. She did not blink to threat and did not follow or look at bright lights. The eye movements were normal. In contrast, she responded to sounds and smiled to her parents' voices. Due to continued shunt malfunction, she had another revision at 4 months of age. Within hours, her sight rapidly began to improve and 2 months later her caregivers felt that her vision was normal. At 4.5 years of age, the neurologic evaluation revealed paraplegia and absent deep tendon reflexes in the lower extremities. The tone was minimally increased in the arms and her hand movements were slightly tremulous. The ophthalmologic examination, including visual acuity 20/20, remained normal. Her intellectual development was age appropriate. Repeated computed tomographic scans showed that the shunt was functioning and visual-evoked potential studies (VEP) showed no abnormalities.

CASE 2.—A male infant was born at 36 weeks' gestation after a normal pregnancy. Hydrocephalus was diagnosed shortly before birth and cephalocentesis was performed. He was delivered by elective cesarean section. Ventriculoperitoneal shunt surgery was performed early in the neonatal period. His computed tomographic scan revealed dilated ventricles, aqueductal stenosis with a corpus callosum abnormality, and migration defects around the sylvian fissures. Although his ocular examination was normal, he had been totally blind since birth. He did not look at bright lights or follow them. He completely ignored his environment visually, although he responded to the voices of his parents. His eye movements were normal, without evidence of nystagmus. At 5 months of age, increased ICP was diagnosed and his shunt was repaired. Within 48 hours his vision rapidly improved to the point where he could follow objects 2 to 3 feet away, but he remained visually inattentive.

At 2 years of age he still had visual inattentiveness and variable vision. His ocular examination remained normal, but measuring his distance visual acuity was impossible because the preferential looking tests suitable for preverbal or multihandicapped children were still not available to us. His development was delayed and he began to have seizures. At age 3.5 years his shunt was still functioning and he was seizure free. His visual acuity, tested by preferential looking tests, was 9.8 cycle per degree, which approximates 20/50 in Snellen measurements.

CASE 3.—A male infant was born at term after a normal pregnancy. An emergency cesarean section was performed because of prolonged labor and fetal distress. The infant was resuscitated. He was noted to have a high lumbar meningomyelocele with paraplegia and hydrocephalus that required ventriculoperitoneal shunting. Computed tomographic scan revealed Chiari II malformation with markedly dilated ventricles. Although his full ocular examination was normal, in his early infancy he completely ignored his visual environment. He did not blink to bright light or to threat. In contrast, he responded to his parents' voices and seemed to enjoy music.

The total blindness persisted until 7 months of age, when a diagnosis of progressive sagittal synostosis was made and corrective surgery was performed. Within 2 to 3 days his vision began to improve, he reached for objects, and a few weeks later he appeared to recognize his parents from across the room. At 10 months of age he was using his sight much more but he was still believed to be visually inattentive.

At the age of 6.5 years, over a period of 4 to 5 months, he gradually lost his vision. Again he became oblivious to his environment visually, but continued to talk. Investigations revealed increased ICP, secondary to small intracranial volume although the shunt was functioning. Reconstructive biparietal craniotomies were performed. Within 48 hours his sight dramatically improved and a few days later his distance Snellen acuity was 20/40 in the left eye and 20/70 in the right eye. At the age of 8 years his vision was the same as before, the funduscopic examination was normal, but on confrontation he appeared to have minimal bilateral peripheral visual loss. He was fully integrated in school, but received learning assistance. He was noted to

The changes in the drawing abilities of patient 3. On the left note the infantile drawing skills during shunt malfunction and on the right the improvement a few days after shunt repair.

be visually inattentive with variable visual function. Psychological testing revealed significant visual perceptual difficulties.

A few months later, his shunt malfunctioned and he began to lose his sight. His teacher observed profound deterioration in his visual skills, his drawing regressed to an infantile state, whereas his verbal abilities and his coordination changed only minimally. However, he frequently gave answers that bore no relationship to the questions. He was referred to an ophthalmologist who did not note any abnormal ocular findings, but found the distance visual acuity to be inconsistent and at best to be 20/200 with correction. The shunt was repaired, and within a couple of days the distance acuity was 20/40 in the left eye and 20/100 in the right eye. His visual-perceptual skills greatly improved (Figure). The neurologic evaluation still showed paraplegia, minimal bilateral peripheral visual field loss on kinetic arc perimetry, and the funduscopic examination remained normal. The VEP and VEP map studies performed postoperatively were also normal.

Due to episodes of increased ICP, this child lost his vision temporarily on two separate occasions. Although the distance visual acuity and visual functioning dramatically improved after surgery, both parents and teachers believed that on each occasion some permanent loss occurred in his visual-perceptual skills. Psychological evaluation substantiated this impression and showed multiple learning disabilities, with visual-perceptual skills being affected the most severely.

COMMENT

These children were born with hydrocephalus. In cases 1 and 3 the diagnosis was meningomyelocele and Chiari II malformation, in case 2 the diagnosis was aqueductal stenosis with congenital anomalies of the brain. The children appeared to be blind from birth until the chronically increased ICP was corrected, and then visual improvement was noted within hours. The process was repeated on three separate occasions in the third child.

The cause of visual impairment was believed to be a disturbance of the visual cortex and optic radiation in all three children. Their eye examinations were always normal. The computed tomographic scans, during shunt failures, revealed markedly dilated occipital horns.

It is known that the latency and amplitude of the VEP components are altered in patients with treated hydrocephalus and those with shunt malfunction.[10] These alterations may be due to papilloedema,[11] anterior pathway compression,[12] stretching of the posterior optic radiation by the enlarged ventricles, or hemisphere ischemia. Abnormalities in the VEP when associated with ventriculomegaly are more obvious with increased ICP.[10] Following shunting or revision, VEPs tend to return to their pretreatment state. Recovery may occur within a few days of treatment or may be more delayed. However, such quick clinical visual improvement after the relief of increased ICP as seen in our cases is unusual because children with various types of long-standing cortical visual impairment tend to regain their sight gradually.[7-9]

The rapid visual improvement seen in these patients suggests that the pathophysiology of blindness might have been prolonged hypoperfusion of the parieto-occipital lobes from chronically increased ICP. This may have been due to posterior cerebral artery compromise secondary to a transtentorial pressure gradient or to direct compression of cerebral tissues. With relief of increased ICP, perfusion to the parieto-occipital areas was reestablished and as a result vision and visual perceptual skills rapidly improved. The visual loss in our patients was severe. It is possible that increased ICP can cause milder forms of visual dysfunction more frequently than apparent, but these children were not referred to clinics or agencies working with the blind and their visual functions were not tested. It is also important to emphasize that long-standing neurologic deficits can be reversed with appropriate control of elevated intracranial pressure.

Most of the children with shunt failures or increased ICP are too sick and/or too young to cooperate with the various Snellen vision charts. On the other hand, the recent introduction of preferential looking or grading acuity tests,[13] which are based on pattern preference, appear to be much more feasible since they require little or no verbal communication.

Cafergot®

(ergotamine tartrate and caffeine) tablets, USP
(ergotamine tartrate and caffeine) suppositories, USP

DESCRIPTION

Cafergot® (ergotamine tartrate and caffeine) Tablet

ergotamine tartrate USP	1 mg
caffeine USP	100 mg

Inactive Ingredients: acacia, carnauba wax, lactose, methylparaben, povidone, propylparaben, sodium benzoate, sorbitol, starch, stearic acid, sucrose, synthetic black ferric oxide, synthetic red ferric oxide, synthetic yellow ferric oxide, talc, tartaric acid, and titanium dioxide.

Cafergot® (ergotamine tartrate and caffeine) Suppository

ergotamine tartrate USP	2 mg
caffeine USP	100 mg

Inactive Ingredients: cocoa butter NF and tartaric acid NF.

Cafergot® (ergotamine tartrate and caffeine) suppositories are *sealed* in foil to afford protection from cocoa butter leakage. If an unavoidable period of exposure to heat softens the suppository, it should be chilled in ice-cold water to solidify it before removing the foil.

ACTIONS: Ergotamine is an alpha adrenergic blocking agent with a direct stimulating effect on the smooth muscle of peripheral and cranial blood vessels and produces depression of central vasomotor centers. The compound also has the properties of serotonin antagonism. In comparison to hydrogenated ergotamine, the adrenergic blocking actions are less pronounced and vasoconstrictive actions are greater.

Caffeine, also a cranial vasoconstrictor, is added to further enhance the vasoconstrictive effect without the necessity of increasing ergotamine dosage.

Many migraine patients experience excessive nausea and vomiting during attacks, making it impossible for them to retain any oral medication. In such cases, therefore, the only practical means of medication is through the rectal route where medication may reach the cranial vessels directly, evading the splanchnic vasculature and the liver.

INDICATIONS

Cafergot® (ergotamine tartrate and caffeine)

Indicated as therapy to abort or prevent vascular headache, e.g., migraine, migraine variants or so-called "histaminic cephalalgia".

CONTRAINDICATIONS: Peripheral vascular disease, coronary heart disease, hypertension, impaired hepatic or renal function, sepsis and pregnancy.

Hypersensitivity to any of the components.

PRECAUTIONS: Although signs and symptoms of ergotism rarely develop even after long term intermittent use of the orally or rectally administered drugs, care should be exercised to remain within the limits of recommended dosage.

Ergotism is manifested by intense arterial vasoconstriction, producing signs and symptoms of peripheral vascular ischemia. Ergotamine induces vasoconstriction by a direct action on vascular smooth muscle. In chronic intoxication with ergot derivatives, headache, intermittent claudication, muscle pains, numbness, coldness and pallor of the digits may occur. If the condition is allowed to progress untreated, gangrene can result.

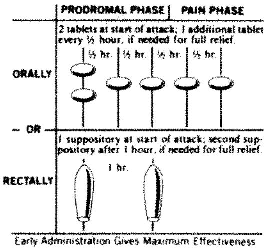
While most cases of ergotism associated with ergotamine treatment result from frank overdosage, some cases have involved apparent hypersensitivity. There are few reports of ergotism among patients taking doses within the recommended limits or for brief periods of time. In rare instances, patients, particularly those who have used the medication indiscriminately over long periods of time, may display withdrawal symptoms consisting of rebound headache upon discontinuation of the drug.

There have been reports of drug abuse and psychological dependence in patients on Cafergot® (ergotamine tartrate and caffeine) therapy. Due to the chronicity of vascular headaches, it is imperative that patients be advised not to exceed recommended dosages with long-term use to avoid ergotism.

ADVERSE REACTIONS: Vasoconstrictive complications, at times of a serious nature, may occur. These include pulselessness, weakness, muscle pains and paresthesias of the extremities and precordial distress and pain. Although these effects occur most commonly with long-term therapy at relatively high doses, they have also been reported with short-term or normal doses. Other adverse effects include transient tachycardia or bradycardia, nausea, vomiting, localized edema and itching.

DOSAGE AND ADMINISTRATION

Procedure: For the best results, dosage should start at the first sign of an attack.



PRODROMAL PHASE
PAIN PHASE
2 tablets at start of attack; 1 additional tablet every ½ hour, if needed for full relief.
½ hr.
½ hr.
½ hr.
½ hr.
ORALLY
— OR
1 suppository at start of attack; second suppository after 1 hour, if needed for full relief.
1 hr.
RECTALLY

Early Administration Gives Maximum Effectiveness

MAXIMUM ADULT DOSAGE

Orally: Total dose for any one attack should not exceed 6 tablets.

Rectally: Two suppositories is the maximum dose for an individual attack.

Total weekly dosage should not exceed 10 tablets or 5 suppositories.

In carefully selected patients, with due consideration of maximum dosage recommendations, administration of the drug at bedtime may be an appropriate short-term preventive measure.

OVERDOSAGE: The toxic effects of an acute overdosage of Cafergot® (ergotamine tartrate and caffeine) are due primarily to the ergotamine component. The amount of caffeine is such that its toxic effects will be overshadowed by those of ergotamine. Symptoms include vomiting, numbness, tingling, pain and cyanosis of the extremities associated with diminished or absent peripheral pulses; hypertension or hypotension; drowsiness, stupor, coma, convulsions and shock. A case has been reported of reversible bilateral papillitis with ring scotomata in a patient who received five times the recommended daily adult dose over a period of 14 days.

Treatment consists of removal of the offending drug by induction of emesis, gastric lavage, and catharsis. Maintenance of adequate pulmonary ventilation, correction of hypotension, and control of convulsions are important considerations. Treatment of peripheral vasospasm should consist of warmth, but not heat, and protection of the ischemic limbs. Vasodilators may be used with benefit but caution must be exercised to avoid aggravating an already existent hypotension.

HOW SUPPLIED

Cafergot® (ergotamine tartrate and caffeine) Tablets

Shell pink colored, sugar coated, imprinted "CAFERGOT" on one side, "S" on other side. Bottles of 250, NDC 0078-0034-28, and cartons of three SigPak® (dispensing unit) packages, each containing 30 tablets in individual blisters, NDC 0078-0034-42.

Cafergot® (ergotamine tartrate and caffeine) Suppositories

Sealed in fuchsia-colored aluminum foil, imprinted "S CAFERGOT® SUPPOSITORY 78-33 SANDOZ". Boxes of 12, NDC 0078-0033-02.

SECOND ANNUAL SYMPOSIUM ON NEUROLOGIC REHABILITATION

HYATT REGENCY HYATT REGENCY BEAVER CREEK RESORT IN THE VAIL VALLEY **BEAVER CREEK COLORADO**

DECEMBER 7 - 11, 1991

Enhancing human performance in neurologic disease

The Second Annual Symposium on Neurologic Rehabilitation is being organized by the Jimmie Heuga Center, a nonprofit, scientific research organization dedicated to reanimating the physically challenged.

The University of Utah School of Medicine jointly sponsors this meeting for continuing medical education in Category 1 of the Physician's Recognition Award of the AMA.

FOR MORE INFORMATION, AND REGISTRATION DETAILS, CONTACT:

Dr. Richard W. Hicks, Executive Director
of the Jimmie Heuga Center at 1-800-367-3101
P.O. BOX 5919
AVON, COLORADO 81620-5919

EEG AND EVOKED POTENTIALS: INTRAOPERATIVE AND ICU MONITORING

January 3 - 5, 1992
The Buena Vista Palace
Lake Buena Vista, Florida
In Walt Disney World Village

Course Directors: Betty Grundy, M.D., Michael Mahla, M.D., and William Friedman, M.D.

FACULTY: Geraldine Chadwick, M.A., C. Michael Harper, M.D., Robin Gilmore, M.D., Rhonda Richards, B.A., Salvatore Goodwin, M.D., Frank Sharbrough, M.D., Kathryn Toney, B.S.

Learn all YOU need to know about EEG and Evoked Potential Monitoring

A distinguished faculty will present indications, methods, and interpretation techniques for EEG and evoked potential monitoring. Participants will be divided into small groups for a more personal, hands-on approach using a wide variety of EEG and evoked potential systems.

Course tuition is $450 ($500 after Nov. 30, 1991). Cancellation of registration by written notification only prior to Dec. 1, 1991. There is a $50 cancellation fee. This program will be approved for Category I credit toward the Physicians Recognition Award of the American Medical Association.

Chewable Tablets of 100 mg—red-speckled, pink   Tablets of 200 mg—pink

WARNING

APLASTIC ANEMIA AND AGRANULOCYTOSIS HAVE BEEN REPORTED IN ASSOCIATION WITH THE USE OF TEGRETOL DATA FROM A POPULATION-BASED CASE CONTROL STUDY DEMONSTRATE THAT THE RISK OF DEVELOPING THESE REACTIONS IS 5-8 TIMES GREATER THAN IN THE GENERAL POPULATION HOWEVER, THE OVERALL RISK OF THESE REACTIONS IN THE UNTREATED GENERAL POPULATION IS LOW, APPROXIMATELY SIX PATIENTS PER ONE MILLION POPULATION PER YEAR FOR AGRANULOCYTOSIS AND TWO PATIENTS PER ONE MILLION POPULATION PER YEAR FOR APLASTIC ANEMIA.

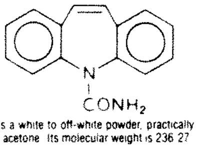
ALTHOUGH REPORTS OF TRANSIENT OR PERSISTENT DECREASED PLATELET OR WHITE BLOOD CELL COUNTS ARE NOT UNCOMMON IN ASSOCIATION WITH THE USE OF TEGRETOL, DATA ARE NOT AVAILABLE TO ESTIMATE ACCURATELY THEIR INCIDENCE OR OUTCOME HOWEVER, THE VAST MAJORITY OF THE CASES OF LEUKOPENIA HAVE NOT PROGRESSED TO THE MORE SERIOUS CONDITIONS OF APLASTIC ANEMIA OR AGRANULOCYTOSIS

BECAUSE OF THE VERY LOW INCIDENCE OF AGRANULOCYTOSIS AND APLASTIC ANEMIA, THE VAST MAJORITY OF MINOR HEMATOLOGIC CHANGES OBSERVED IN MONITORING OF PATIENTS ON TEGRETOL ARE UNLIKELY TO SIGNAL THE OCCURRENCE OF EITHER ABNORMALITY NONETHELESS, COMPLETE PRETREATMENT HEMATOLOGICAL TESTING SHOULD BE OBTAINED AS A BASELINE IF A PATIENT IN THE COURSE OF TREATMENT EXHIBITS LOW OR DECREASED WHITE BLOOD CELL OR PLATELET COUNTS, THE PATIENT SHOULD BE MONITORED CLOSELY DISCONTINUATION OF THE DRUG SHOULD BE CONSIDERED IF ANY EVIDENCE OF SIGNIFICANT BONE MARROW DEPRESSION DEVELOPS

Before prescribing Tegretol, the physician should be thoroughly familiar with the details of this prescribing information, particularly regarding use with other drugs, especially those which accentuate toxicity potential.

DESCRIPTION

Tegretol, carbamazepine USP, is an anticonvulsant and specific analgesic for trigeminal neuralgia, available as chewable tablets of 100 mg and tablets of 200 mg for oral administration Its chemical name is 5H-dibenz[b,f]azepine-5-carboxamide, and its structural formula is



Carbamazepine USP is a white to off-white powder, practically insoluble in water and soluble in alcohol and in acetone Its molecular weight is 236 27

Inactive Ingredients. Colloidal silicon dioxide, FD&C Red No 3 (chewable tablets only), FD&C Red No. 40 (200-mg tablets only), flavoring (chewable tablets only), gelatin, glycerin, magnesium stearate, sodium starch glycolate (chewable tablets only), starch stearic acid, and sucrose (chewable tablets only)

CLINICAL PHARMACOLOGY

In controlled clinical trials, Tegretol has been shown to be effective in the treatment of psychomotor and grand mal seizures, as well as trigeminal neuralgia

It has demonstrated anticonvulsant properties in rats and mice with electrically and chemically induced seizures It appears to act by reducing polysynaptic responses and blocking the post-tetanic potentiation. Tegretol greatly reduces or abolishes pain induced by stimulation of the infraorbital nerve in cats and rats It depresses thalamic potential and bulbar and polysynaptic reflexes, including the linguomandibular reflex in cats Tegretol is chemically unrelated to other anticonvulsants or other drugs used to control the pain of trigeminal neuralgia The mechanism of action remains unknown

Tegretol tablets are adequately absorbed after oral administration at a slower rate than a solution, thus avoiding undesirably high peak concentrations Tegretol chewable tablets may produce higher peak levels than the same dose given as regular tablets Tegretol in blood is 76% bound to plasma proteins Plasma levels of Tegretol are variable and may range from 0.5-25 μg/ml, with no apparent relationship to the daily intake of the drug Usual adult therapeutic levels are between 4 and 12 μg/ml Following oral administration, serum levels peak at 4 to 5 hours The CSF/serum ratio is 0 22, similar to the 22% unbound Tegretol in serum Because Tegretol may induce its own metabolism, the half-life is also variable Initial half-life values range from 25-65 hours, with 12-17 hours on repeated doses Tegretol is metabolized in the liver. After oral administration of 14C-carbamazepine, 72% of the administered radioactivity was found in the urine and 28% in the feces This urinary radioactivity was composed largely of hydroxylated and conjugated metabolites, with only 3% of unchanged Tegretol Transplacental passage of Tegretol is rapid (30 to 60 minutes), and the drug is accumulated in fetal tissues, with higher levels found in liver and kidney than in brain and lungs

INDICATIONS AND USAGE

Epilepsy: Tegretol is indicated for use as an anticonvulsant drug Evidence supporting efficacy of Tegretol as an anticonvulsant was derived from active drug-controlled studies that enrolled patients with the following seizure types

1 Partial seizures with complex symptomatology (psychomotor, temporal lobe) Patients with these seizures appear to show greater improvement than those with other types
2 Generalized tonic-clonic seizures (grand mal)
3 Mixed seizure patterns which include the above, or other partial or generalized seizures

Absence seizures (petit mal) do not appear to be controlled by Tegretol (see PRECAUTIONS, General)

Trigeminal Neuralgia: Tegretol is indicated in the treatment of the pain associated with true trigeminal neuralgia

Beneficial results have also been reported in glossopharyngeal neuralgia

This drug is not a simple analgesic and should not be used for the relief of trivial aches or pains

CONTRAINDICATIONS

Tegretol should not be used in patients with a history of previous bone marrow depression, hypersensitivity to the drug, or known sensitivity to any of the tricyclic compounds, such as amitriptyline, desipramine, imipramine, protriptyline, nortriptyline, etc. Likewise, on theoretical grounds its use with monoamine oxidase inhibitors is not recommended Before administration of Tegretol, MAO inhibitors should be discontinued for a minimum of fourteen days, or longer if the clinical situation permits

WARNINGS

Patients with a history of adverse hematologic reaction to any drug may be particularly at risk

Severe dermatologic reactions including toxic epidermal necrolysis (Lyell's syndrome) and Stevens-Johnson syndrome, have been reported with Tegretol These reactions have been extremely rare However, a few fatalities have been reported

Tegretol has shown mild anticholinergic activity, therefore, patients with increased intraocular pressure should be closely observed during therapy

Because of the relationship of the drug to other tricyclic compounds, the possibility of activation of a latent psychosis and, in elderly patients, of confusion or agitation should be borne in mind

PRECAUTIONS

General: Before initiating therapy, a detailed history and physical examination should be made

Tegretol should be used with caution in patients with a mixed seizure disorder that includes atypical absence seizures, since in these patients Tegretol has been associated with increased frequency of generalized convulsions (see INDICATIONS AND USAGE)

Therapy should be prescribed only after critical benefit-to-risk appraisal in patients with a history of cardiac, hepatic or renal damage, adverse hematologic reaction to other drugs, or interrupted courses of therapy with Tegretol

Information for Patients: Patients should be made aware of the early toxic signs and symptoms of a potential hematologic problem, such as fever, sore throat, ulcers in the mouth, easy bruising, petechial or purpuric hemorrhage and should be advised to report to the physician immediately if any such signs or symptoms appear

Since dizziness and drowsiness may occur, patients should be cautioned about the hazards of operating machinery or automobiles or engaging in other potentially dangerous tasks

Laboratory Tests: Complete pretreatment blood counts, including platelets and possibly reticulocytes and serum iron, should be obtained as a baseline If a patient in the course of treatment exhibits low or decreased white blood cell or platelet counts, the patient should be monitored closely Discontinuation of the drug should be considered if any evidence of significant bone marrow depression develops

Baseline and periodic evaluations of liver function, particularly in patients with a history of liver disease, must be performed during treatment with this drug since liver damage may occur The drug should be discontinued immediately in cases of aggravated liver dysfunction or active liver disease

Baseline and periodic eye examinations, including slit-lamp, funduscopy and tonometry, are recommended since many phenothiazines and related drugs have been shown to cause eye changes

Baseline and periodic complete urinalysis and BUN determinations are recommended for patients treated with this agent because of observed renal dysfunction

Monitoring of blood levels (see CLINICAL PHARMACOLOGY) has increased the efficacy and safety of anticonvulsants This monitoring may be particularly useful in cases of dramatic increase in seizure frequency and for verification of compliance In addition, measurement of drug serum levels may aid in determining the cause of toxicity when more than one medication is being used

Thyroid function tests have been reported to show decreased values with Tegretol administered alone

Hyponatremia has been reported in association with Tegretol use, either alone or in combination with other drugs

Drug Interactions: The simultaneous administration of phenobarbital, phenytoin, or primidone or a combination of two produces a marked lowering of serum levels of Tegretol The effect of valproic acid on Tegretol blood levels is not clearly established, although an increase in the ratio of active 10, 11-epoxide metabolite to parent compound is a consistent finding

The half-lives of phenytoin, warfarin, doxycycline, and theophylline were significantly shortened when administered concurrently with Tegretol Haloperidol and valproic acid serum levels may be reduced when these drugs are administered with Tegretol The doses of these drugs may therefore have to be increased when Tegretol is added to the therapeutic regimen

Concomitant administration of Tegretol with erythromycin, cimetidine, propoxyphene isoniazid or calcium channel blockers has been reported to result in elevated plasma levels of carbamazepine resulting in toxicity in some cases Also, concomitant administration of carbamazepine and lithium may increase the risk of neurotoxic side effects

Alterations of thyroid function have been reported in combination therapy with other anticonvulsant medications

Breakthrough bleeding has been reported among patients receiving concomitant oral contraceptives and their reliability may be adversely affected

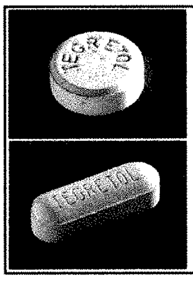
Carcinogenesis, Mutagenesis, Impairment of Fertility: Carbamazepine, when administered to Sprague-Dawley rats for two years in the diet at doses of 25, 75 and 250 mg/kg/day, resulted in a dose-related increase in the incidence of hepatocellular tumors in females and of benign interstitial cell adenomas in the testes of males

Carbamazepine must, therefore, be considered to be carcinogenic in Sprague-Dawley rats Bacterial and mammalian mutagenicity studies using carbamazepine produced negative results The significance of these findings relative to the use of carbamazepine in humans is at present, unknown

Pregnancy Category C: Tegretol has been shown to have adverse effects in reproduction studies in rats when given orally in dosages 10-25 times the maximum human daily dosage of 1200 mg In rat teratology studies, 2 of 135 offspring showed kinked ribs at 250 mg/kg and 4 of 119 offspring at 650 mg/kg showed other anomalies (cleft palate 1 talipes, 1, anophthalmos, 2) In reproduction studies in rats, nursing offspring demonstrated a lack of weight gain and an unkempt appearance at a maternal dosage level of 200 mg/kg

There are no adequate and well-controlled studies in pregnant women Epidemiological data suggest that there may be an association between the use of carbamazepine during pregnancy and congenital malformations, including spina bifida Tegretol should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus

Retrospective case reviews suggest that compared with monotherapy there may be a higher prevalence of teratogenic effects associated with the use of anticonvulsants in combination therapy Therefore, monotherapy is recommended for pregnant women



Only TEGRETOL,
brand of carbamazepine,
provides the prescribing
flexibility of a 100-mg scored
chewable tablet, as well as
a 200-mg scored tablet.

It is important to note that anticonvulsant drugs should not be discontinued in patients in whom the drug is administered to prevent major seizures because of the strong possibility of precipitating status epilepticus with attendant hypoxia and threat to life In individual cases where the severity and frequency of the seizure disorder are such that removal of medication does not pose a serious threat to the patient, discontinuation of the drug may be considered prior to and during pregnancy, although it cannot be said with any confidence that even minor seizures do not pose some hazard to the developing embryo or fetus

Labor and Delivery: The effect of Tegretol on human labor and delivery is unknown

Nursing Mothers: During lactation, concentration of Tegretol in milk is approximately 60% of the maternal plasma concentration

Because of the potential for serious adverse reactions in nursing infants from carbamazepine, a decision should be made whether to discontinue nursing or to discontinue the drug taking into account the importance of the drug to the mother

Pediatric Use: Safety and effectiveness in children below the age of 6 years have not been established

ADVERSE REACTIONS

If adverse reactions are of such severity that the drug must be discontinued, the physician must be aware that abrupt discontinuation of any anticonvulsant drug in a responsive epileptic patient may lead to seizures or even status epilepticus with its life-threatening hazards

The most severe adverse reactions have been observed in the hemopoietic system (see boxed WARNING), the skin and the cardiovascular system

The most frequently observed adverse reactions, particularly during the initial phases of therapy, are dizziness, drowsiness, unsteadiness, nausea, and vomiting To minimize the possibility of such reactions, therapy should be initiated at the low dosage recommended

The following additional adverse reactions have been reported

Hemopoietic System Aplastic anemia, agranulocytosis, pancytopenia, bone marrow depression, thrombocytopenia, leukopenia, leukocytosis, eosinophilia, acute intermittent porphyria

Skin Pruritic and erythematous rashes urticaria, toxic epidermal necrolysis (Lyell's syndrome) (see WARNINGS), Stevens-Johnson syndrome (see WARNINGS), photosensitivity reactions, alterations in skin pigmentation, exfoliative dermatitis erythema multiforme and nodosum, purpura, aggravation of disseminated lupus erythematosus, alopecia and diaphoresis In certain cases, discontinuation of therapy may be necessary

Cardiovascular System Congestive heart failure, edema, aggravation of hypertension, hypotension, syncope and collapse, aggravation of coronary artery disease, arrhythmias and AV block, primary thrombophlebitis, recurrence of thrombophlebitis and adenopathy or lymphadenopathy

Some of these cardiovascular complications have resulted in fatalities Myocardial infarction has been associated with other tricyclic compounds

Liver Abnormalities in liver function tests, cholestatic and hepatocellular jaundice, hepatitis

Respiratory System Pulmonary hypersensitivity characterized by fever, dyspnea, pneumonitis or pneumonia

Genitourinary System Urinary frequency, acute urinary retention, oliguria with elevated blood pressure, azotemia, renal failure, and impotence Albuminuria, glycosuria elevated BUN and microscopic deposits in the urine have also been reported

Testicular atrophy occurred in rats receiving Tegretol orally from 4 to 52 weeks at dosage levels of 50 to 400 mg/kg/day Additionally, rats receiving Tegretol in the diet for two years at dosage levels of 25, 75, and 250 mg/kg/day had a dose-related incidence of testicular atrophy and aspermatogenesis In dogs, it produced a brownish discoloration, presumably a metabolite, in the urinary bladder at dosage levels of 50 mg/kg and higher Relevance of these findings to humans is unknown

Nervous System Dizziness, drowsiness, disturbances of coordination, confusion, headache, fatigue, blurred vision, visual hallucinations, transient diplopia, oculomotor disturbances, nystagmus, speech disturbances, abnormal involuntary movements, peripheral neuritis and paresthesias, depression with agitation, talkativeness, tinnitus, and hyperacusis

There have been reports of associated paralysis and other symptoms of cerebral arterial insufficiency, but the exact relationship of these reactions to the drug has not been established

Digestive System Nausea, vomiting gastric distress and abdominal pain, diarrhea, constipation anorexia, and dryness of the mouth and pharynx, including glossitis and stomatitis

Eyes Scattered, punctate, cortical lens opacities, as well as conjunctivitis have been reported Although a direct causal relationship has not been established, many phenothiazines and related drugs have been shown to cause eye changes

Musculoskeletal System Aching joints and muscles, and leg cramps

Metabolism Fever and chills Inappropriate antidiuretic hormone (ADH) secretion syndrome has been reported Cases of frank water intoxication, with decreased serum sodium (hyponatremia) and confusion, have been reported in association with Tegretol use (see PRECAUTIONS, Laboratory Tests)

Other Isolated cases of a lupus erythematosus-like syndrome have been reported There have been occasional reports of elevated levels of cholesterol, HDL cholesterol and triglycerides in patients taking anticonvulsants

A case of aseptic meningitis accompanied by myoclonus and peripheral eosinophilia, has been reported in a patient taking carbamazepine in combination with other medications The patient was successfully dechallenged and the meningitis reappeared upon rechallenge with carbamazepine

DRUG ABUSE AND DEPENDENCE

No evidence of abuse potential has been associated with Tegretol nor is there evidence of psychological or physical dependence in humans

OVERDOSAGE

Acute Toxicity

Lowest known lethal dose adults >60 g (39-year-old man) Highest known doses survived adults, 30 g (31-year-old woman), children 10 g (6-year-old boy) small children, 5 g (3-year-old girl)

Oral LD50 in animals (mg/kg) mice, 1100-3750 rats, 3850-4025 rabbits 1500-2680 guinea pigs 920

Signs and Symptoms

The first signs and symptoms appear after 1-3 hours Neuromuscular disturbances are the most prominent Cardiovascular disorders are generally milder, and severe cardiac complications occur only when very high doses (>60 g) have been ingested

Respiration Irregular breathing respiratory depression

Cardiovascular System Tachycardia, hypotension or hypertension, shock conduction disorders

Nervous System and Muscles Impairment of consciousness ranging in severity to deep coma Convulsions especially in small children Motor restlessness muscular twitching tremor, athetoid movements, opisthotonos ataxia, drowsiness, dizziness, mydriasis, nystagmus, adiadochokinesia, ballism psychomotor disturbances, dysmetria initial hyperreflexia followed by hyporeflexia

Gastrointestinal Tract Nausea, vomiting

Kidneys and Bladder Anuria or oliguria, urinary retention

Laboratory Findings Isolated instances of overdosage have included leukocytosis, reduced leukocyte count, glycosuria and acetonuria EEG may show dysrhythmias

Combined Poisoning When alcohol tricyclic antidepressants barbiturates or hydantoins are taken at the same time the signs and symptoms of acute poisoning with Tegretol may be aggravated or modified

Treatment

The prognosis in cases of severe poisoning is critically dependent upon prompt elimination of the drug which may be achieved by inducing vomiting irrigating the stomach, and by taking appropriate steps to diminish absorption If these measures cannot be implemented without risk on the spot the patient should be transferred at once to a hospital while ensuring that vital functions are safeguarded There is no specific antidote

Elimination of the Drug Induction of vomiting

Gastric lavage Even when more than 4 hours have elapsed following ingestion of the drug the stomach should be repeatedly irrigated especially if the patient has also consumed alcohol

Measures to Reduce Absorption Activated charcoal, laxatives

Measures to Accelerate Elimination Forced diuresis

Dialysis is indicated only in severe poisoning associated with renal failure Replacement transfusion is indicated in severe poisoning in small children

Respiratory Depression Keep the airways free, resort, if necessary, to endotracheal intubation, artificial respiration, and administration of oxygen

Hypotension Shock Keep the patient's legs raised and administer a plasma expander If blood pressure fails to rise despite measures taken to increase plasma volume use of vasoactive substances should be considered

Convulsions Diazepam or barbiturates

Warning Diazepam or barbiturates may aggravate respiratory depression (especially in children) hypotension and coma However barbiturates should not be used if drugs that inhibit monoamine oxidase have also been taken by the patient either in overdosage or in recent therapy (within one week)

Surveillance Respiration, cardiac function (ECG monitoring), blood pressure body temperature pupillary reflexes and kidney and bladder function should be monitored for several days

Treatment of Blood Count Abnormalities If evidence of significant bone marrow depression develops, the following recommendations are suggested (1) stop the drug, (2) perform daily CBC platelet and reticulocyte counts (3) do a bone marrow aspiration and trephine biopsy immediately and repeat with sufficient frequency to monitor recovery

Special periodic studies might be helpful as follows (1) white cell and platelet antibodies (2) 59Fe—ferrokinetic studies (3) peripheral blood cell typing, (4) cytogenetic studies on marrow and peripheral blood, (5) bone marrow culture studies for colony-forming units (6) hemoglobin electrophoresis for A_2 and F hemoglobin, and (7) serum folic acid and B_{12} levels

A fully developed aplastic anemia will require appropriate intensive monitoring and therapy, for which specialized consultation should be sought

DOSAGE AND ADMINISTRATION

Monitoring of blood levels has increased the efficacy and safety of anticonvulsants (see PRECAUTIONS, Laboratory Tests) Dosage should be adjusted to the needs of the individual patient A low initial daily dosage with a gradual increase is advised As soon as adequate control is achieved, the dosage may be reduced very gradually to the minimum effective level Tablets should be taken with meals

Epilepsy (see INDICATIONS AND USAGE)

Adults and children over 12 years of age—Initial: 200 mg b i d Increase at weekly intervals by adding up to 200 mg per day using a t i d or q i d regimen until the best response is obtained Dosage should generally not exceed 1000 mg daily in children 12 to 15 years of age and 1200 mg daily in patients above 15 years of age Doses up to 1600 mg daily have been used in adults in rare instances ***Maintenance***: Adjust dosage to the minimum effective level, usually 800-1200 mg daily

Children 6-12 years of age—Initial: 100 mg b i d Increase at weekly intervals by adding 100 mg per day using a t i d or q i d regimen until the best response is obtained Dosage should generally not exceed 1000 mg ***Maintenance***: Adjust dosage to the minimum effective level usually 400-800 mg daily

Combination Therapy: Tegretol may be used alone or with other anticonvulsants When added to existing anticonvulsant therapy, the drug should be added gradually while the other anticonvulsants are maintained or gradually decreased except phenytoin, which may have to be increased (see PRECAUTIONS, Drug Interactions and Pregnancy Category C)

Trigeminal Neuralgia (see INDICATIONS AND USAGE)

Initial: 100 mg b i d on the first day for a total daily dose of 200 mg This daily dose may be increased by up to 200 mg a day using increments of 100 mg every 12 hours only as needed to achieve freedom from pain Do not exceed 1200 mg daily

Maintenance: Control of pain can be maintained in most patients with 400 mg to 800 mg daily However, some patients may be maintained on as little as 200 mg daily while others may require as much as 1200 mg daily At least once every 3 months throughout the treatment period attempts should be made to reduce the dose to the minimum effective level or even to discontinue the drug

HOW SUPPLIED

Chewable Tablets 100 mg—round, red-speckled, pink, single-scored (imprinted Tegretol on one side and 52 twice on the scored side)

Bottles of 100	NDC 0028-0052-01
Unit Dose (blister pack) Box of 100 (strips of 10)	NDC 0028-0052-61

Tablets 200 mg—capsule-shaped, pink, single-scored (imprinted Tegretol on one side and 27 twice on the scored side)

Bottles of 100	NDC 0028-0027-01

A Translation of Otto Binswanger's Article, 'The Delineation of the Generalized Progressive Paralyses'

John P. Blass, MD, PhD; Siegfried Hoyer, MD; Roger Nitsch, MD

The task with which the esteemed committee of our society has charged me, that is, the introduction of the discussion on the definition of generalized progressive paresis by the characterization of the important aspects of the condition, can be divided into three parts: (1) consideration of the anatomic criteria, (2) the causes, and (3) the clinical course.

I shall attempt a brief examination of those of the characteristic features of progressive paresis that allow its differential diagnosis from other similar and related conditions, basing my considerations on all three of these aspects. I hope I may be allowed to observe, however, that the limited scope of this short report will allow me to do no more than give an imprecise indication of the clinical picture and that I hope a more exact representation of the whole or of individual parts of the whole will emerge from the discussion.

The first question, that of the anatomic characteristics of generalized progressive paresis, has been the subject of lively controversies, particularly in recent years. One needs only to recall the debates at the International Congress in Berlin, which most clearly reflect the fundamentally different opinions that still exist concerning this subject. I, myself, during the course of a more detailed treatment of the histologic findings, have lately attempted to delineate the primary impairments and to put forward their relationships to the tissue changes, which in the correct light appear to be secondary, insofar as these concern the cerebral cortex.

However, before we look at these anatomic details, which are still largely unexplained, we shall have to devote ourselves to the task of examining whether perhaps even the macroscopic postmortem findings alone offer us a way to discriminate progressive paresis unequivocally from other organic brain diseases.

The most important observations in the brain of a person with paresis are (1) reduction in brain weight; (2) atrophy of the cortex of the frontal and parietal lobes, the insular gyri, and the anterior portion of the temporal lobe; (3) expansion of the ventricles, internal hydrocephalus, and granular ependymitis; (4) external hydrocephalus, generalized brain edema, and chronic leptomeningitis; and (5) hemorrhagic pachymeningitis. (Changes in the substance of the spinal cord are deliberately not considered here, as they can hardly give rise to diagnostic errors in the assessment of anatomic findings. At most, it seems possible that in cases of tabetic paralysis, the less easily recognized macroscopic changes in the brain might be overlooked during the anatomic examination because of pronounced and unequivocal changes in the spinal cord. This is possible if the clinical signs and symptoms of the illness are unknown to the anatomist. The importance of spinal cord involvement in the pathologic process of progressive paresis has been described in articles published by Westphal and more recently by Fürstner.)

In the final picture of progressive paresis, we regularly find either all the postmortem findings listed herein in their entirety or at least some of them; nonetheless, no one should succumb to the temptation to come to either a positive or a negative conclusion on the basis of the presence or absence of only one of these features.

The first of the above observations that I intend to discuss are the changes attributable to leptomeningitis. Earlier, particularly under the influence of the work performed by Duchek and Meyer, the opinion prevailed that the meningitis-induced changes were actually the most obvious and, indeed, the primary pathologic processes in progressive paresis and, in accordance with this, that these changes were always present in the typical cases of this illness. Varied experience collected later, however, has proved that even in cases of long-standing progressive paresis, there is occasionally no evidence of any serious change attributable to meningitis. According to my own observations collected from patients in the clinic in Jena, among 106 postmortem examinations, 70 cases with pronounced leptomeningitis-induced changes were recorded, 28 with slight changes of this kind and eight with no sign whatsoever of such changes. In the cases with only slight involvement of the soft meninges, there were only intermittent whitish, cloudy areas or streaky thickenings along the greater vascular trunks. Similar observations are recorded in the brains of nonparetic individuals of the same age who have lived in similar circumstances. The extensive whitish, cloudy patches on the convex surface of the hemisphere, the fine granular grayish white and grayish-yellow deposits in the subarachnoid spaces, the plateletlike thickenings of the pia mater in the region of Magendi's foramen, the large transverse fissure of the brain, the optic chiasm, and the sylvian fissure are not present in these brains. The meninges can almost always be easily separated from the surface of the brain, with no superficial loss of substance; only at isolated points over the frontal lobe, especially over the gyrus rectus, we detach small particles from the glial coating and the uppermost layer of the cortex in the area of the incoming cortical vessels together with the pia mater. If even slight brain edema is present, extending the epicerebral spaces, these adhesions are also not observed. We deduce from this that there are very definitely pronounced cases of progres-

Dr Nitsch is now with the Department of Neurology, Massachusetts General Hospital, Boston.

Presented at the annual meeting of the Society of German Alienists, Dresden, East Germany, September 20, 1894.

Reprint requests to the Burke Rehabilitation Center, 785 Mamaroneck Ave, White Plains, NY 10605 (Dr Blass).

sive paresis in which the so-called characteristic leptomeningitic changes are present only to a very slight degree or not at all.

The reduction in brain weight is regarded as the second most characteristic feature. It is certainly true that we shall be able to show quite a considerable reduction in the average brain weight (by 100 g and more) in the overwhelming majority of brains from elderly patients, especially if we have taken away the ventricular fluid and the edematous meninges. Nonetheless, I should like to pronounce a caveat against the assumption that every case of progressive paresis that has marked clinical features and is observed in an elderly patient must be accompanied by a reduction of this degree in brain weight. I have seen a number of unequivocal cases of progressive paresis in which death had supervened in the terminal stage and in which no substantial reduction in the brain weight was present. The volume of the brain should always be considered in conjunction with the overall body height and weight before a correct estimate of the average weight appropriate to the particular brain can be made. (A more detailed compilation of the macroscopic postmortem findings recorded in studies of patients who died with paresis from 1882 to 1894 in the clinic in Jena is to be published shortly by a colleague and former student of mine.)

There is another feature that is just as variable and unreliable: macroscopically visible atrophy of the cerebral cortex. For my present purposes, I disregard the generally familiar typical findings with widely yawning sulci and the narrowing of the frontal lobe gyri to narrow ridges, as these preclude difficulties when the diagnosis is made. Besides these findings, there are others, including the high-grade mental deterioration progressing over years of illness to complete devastation, which is in stark contrast to the macroscopically apparent destruction of specific cortical tissue. One is always newly surprised when neither examination of the brain surface nor the study of vertical sections of the hemispheres reveals demonstrable cortical atrophy. Of course, I am not thinking now of brains in which the cortical atrophy is obscured by a rather pronounced edematous saturation of the cerebral cortex and fissuring of the glia, often to a substantial degree (particularly in the second cortical layer and in the medullary lamina). (Unfortunately, no comprehensive measurements are available that could provide us with average values for the width of the cortex in the individual gyri. Even now, we therefore still have access only to extremely unreliable estimates, which mostly are of only very limited value to the observer. As yet, we are only in a position to recognize substantial wasting of the cortex; if this is not present in elderly patients with paresis, the interpretation of the degree of cortical atrophy varies widely among different examiners, as experience has shown me many times.)

If we recall the finer anatomic processes involved in the progression of the paretic condition, it becomes easy to understand that the destruction of the functional cortical tissue can be almost completely compensated for by reparatory proliferations of the connective tissue containing the vessels. This will be true particularly if the onset of the illness is at a relatively early age, while the glial tissue still has a very strong growth tendency.

With this, we come closer to the less numerous cases of diffuse brain sclerosis, which is known to be confined exclusively to childhood and early youth and has been described in some detail by Strümpell, Siemens, Schultze, Jendrassik, Marie, and others. This diffuse proliferation of the glial tissue, which substitutes for the specific neural tissue that has not developed completely, only rarely leads to pronounced thinning of the cerebral cortex. When cut through, the cortex is more likely to appear expanded and pale grayish white; an insight into the nature of the illness is not provided until the microscopic examination is performed. Confusion with progressive paresis will be possible when, on the one hand, following a long course of the illness, death does not occur until the patient is at an age at which the paretic condition is also pronounced, and, on the other hand, when the paretic condition occurs while the patient is still young. I refer you to the cases of juvenile paralysis reported in the psychiatric literature during the last two decades. In the second type of case mentioned above in particular, errors in diagnosis are probably not uncommon, as there is by no means a sharp discrimination between the clinical pictures of juvenile paralysis and diffuse cerebral sclerosis. A strict distinction can be made during an anatomic examination: diffuse cerebral sclerosis is characterized as a primary proliferation of the glial parts with simultaneous or rather earlier inhibition of the development of the neural elements (this glial proliferation can be explained by two different processes: [1] excessive growth of histologically unfinished ectodermal tissue components takes place or [2] the mesodermal parts of the connective tissue penetrating with the vessels show pathologically intensified growth and fill up the defects that have arisen as a consequence of the inhibited development of the ectodermal tissue); the paralysis presupposes the destruction of fully developed neural elements; and the glial proliferations in this case are secondary processes of repair. I am, of course, not unaware that this separation of the two pathologic processes—which is a scientific necessity—is countered by very considerable problems in practice when actual patients are examined.

Gliosis of the cerebral cortex, which was first reported by Fürstner, is more easily differentiated from paralysis. It has one feature that is completely peculiar to it, namely, the presence of tuberosities and granules extending beyond the surface of the brain and tending to form cavities in their interior. The only difference between this condition and diffuse sclerosis of the brain, I suppose, is its focal nature.

One of the most unequivocal features, in my opinion, is granular ependymitis. In my experience, this is never absent in progressive paresis. It must be mentioned that the granulations are not always very substantial. We find them occasionally only in the hindmost parts of the floor of the rhomboid fossa at the outermost border of the alae cinereae and at the lateral declivities of the roof of the fourth ventricle. Otherwise, they are most easily found at the outermost border of the strial callosities in the lateral ventricle.

I do not mean to say that these ependymal proliferations occur exclusively in the presence of general paresis. We encounter them occasionally in other organic brain diseases, particularly in the presence of brain tumors. I have also found distinct granular ependymitis in a few instances following so-called functional psychoses; these were in persons who had suffered from chronic paranoia and who had died at a fairly good age (between 50 and 60 years). There was certainly no relationship between this postmortem finding and the known psychosis; rather, it must be assumed that in these cases, complications are present as characterized by organic alterations in the brain that have superimposed themselves on the earlier pathologic process. Thus, we cannot say that the presence of granular ependymitis is an unmistakable sign of progressive paresis. In my opinion, however, the inverse of this conclusion is very well justified, namely, that if granular ependymitis is not present, the diagnosis of progressive paresis will be very dubious.

I have found it necessary to recognize the value of the macroscopically visible features of the postmortem findings in more detail, because in practice they are virtually the only basis for a diagnosis of paresis on the mortuary bench. In the case of forensic examinations, in particular, the conclusions drawn from these macroscopic observations can result in very important implications.

It can be inferred from the above discussion that the anatomic diagnosis of this illness is by no means confirmed by the presence of just one macroscopic finding that is also found in paresis. Anything more than the absence of one of the so-called typical alterations justifies its exclusion. The anatomic diagnosis, however, is ensured when several of these typical features are present simultaneously.

At our present state of knowledge, the microscopic examination poses many difficulties in diagnosis. In elderly patients in whom the macroscopically recognizable changes are distinctly pronounced, the microscopic examination also unequivocally shows the final results of chronically progressive wasting of the functional cortical tissue (wasting of the myelinated nerve fibers and destruction of the ganglion cells in places) in association with degenerative alterations in the vessel walls and reparatory formation of the interstitial tissue. In such circumstances, the first things to come to notice are hyaline degeneration and streaky thickening of blood vessels with endothelial proliferations; extravasations of blood and conglomerations of lymph corpuscles in the intravascular and extravascular lymphatic spaces, which are dilated in parts; rigid, thickened, fibrous interstitial tissue, especially in the outer layers of the cortex and in the glial coating; abundant astrocytes and so-called free nuclei; and leptomeningitic scars with proliferations and accumulations of nuclei within the endothelial membrane, while the nerve tissue defect cannot be established until more laborious comparative investigations are performed.

In the case of the so-called early forms, that is, in patients in whom both the onset and the course are chronic and who have died of intercurrent diseases during the initial stages of the paresis, as in the cases in which the paresis has taken a rapid course, demonstration of the condition based on anatomic examination findings is much more complicated. The so-called chronically inflammatory, ie, reparatory, processes cannot be detected with any degree of certainty or at least not with the methods of investigation used thus far, as only the degenerative and atrophic alterations become clearly apparent when these methods are applied. In the same way, the finer alterations in the ganglion cells and the nerve fibers can be detected only incompletely with the aids available; only the advanced degeneration and degenerative alterations of the ganglion cells and the wasting of the coarser nerve myelinated fibers can be distinguished, while so far the incipient affliction of the nerve cell, the function of which can be profoundly impaired even at such an early stage, and the involvement of the finer nerve plexus, which doubtless has a high functional importance, remain completely undisclosed.

We shall not come any closer to an answer to the first problem until the cell studies introduced by Nissl have been further refined; at the same time, we may hope that Golgi's method can be adapted for use in research on paresis. Nonetheless, the very important question of the involvement of the ectodermal components of the glial tissue in the pathologic process must also be freshly investigated as soon as the details of Weigert's method of glia staining are made known.

Up to the present, we are not in a position to say any more than that following death at an advanced stage or in the terminal stage of the disease after a chronic course, histologic examination discloses easily recognizable alterations of the cerebral cortex. These, however, are of relatively little importance in the differential diagnosis, because, as you know, precisely in these cases the diagnosis can easily be made based on the postmortem macroscopic findings.

In cases with what might be referred to as a rapid course, that is, when the entire duration of the illness is compressed into a few months, histologic examination yields highly characteristic, easily recognizable pictures if the so-called inflammatory phenomena have developed early or if extensive degenerative processes of the vessels (mostly of the nature of hyaline degeneration) are present. In the latter case, we find numerous massive accumulations of red blood corpuscles or blood pigment bodies in the intravascular and extravascular lymph spaces, so that it is also permissible to refer to a hemorrhagic form of paralysis. [*Editor's note: The second part of the three-part article, "Continuation," follows.*]

I will follow this critical review of the anatomic alterations in progressive paresis with a brief description of the postmortem findings that can be observed in two pathologic forms that are reminiscent of the clinical manifestations of paresis. First, I should like to draw attention to a relatively small group of cases (in the last 11 years, that is, since I became aware of this pathologic form, only eight such instances have come to my attention), in each of which a closer examination was necessary later in the course of the differential diagnosis. In this group, we find pronounced atrophy of the white matter, either confined to one or more gyri of the brain or in several sections of the hemisphere at the same time, varying only in intensity. In the most severe cases, the entire white matter of a cerebral lobe appears to have completely wasted away, so that the opposing gyri with the thread of medulla are touching each other, for example, in the region of the insula, or are only bound on the inside by the thickened ependyma of the enormously expanded ventricular segments. These alterations are seen most clearly in the occipital and temporal lobes, so that the lower and posterior horns of the ventricles are transformed to wide cavities with blind endings, while the anterior segment of the lateral ventricle is expanded relatively little and the white matter in the frontal lobe is almost uninvolved in the disease process. Even the fact that the main seat of the illness is in the posterior segments of the brain is a way to discriminate these cases from progressive paresis. The clinical manifestations and the course of illness are also characterized by features that allow a reliable differentiation from paresis. It will be best to refer to this form of illness as *encephalitis subcorticalis chronica progressiva* (the term *encephalitis* is used here, as by Thoma, in the wider sense of brain disease and not to mean inflammation of the brain) [*editor's note: translator's emphasis*].

On macroscopic examination, the cortex shows no essential changes, except for slight thinning. Granular ependymitis was seen in only four cases. The disease process begins in some cases during the same period in life as paresis also appears, ie, in the second half of the fifth decade. There is no doubt, however, that it begins far more frequently in persons on the threshold of old age, in the early 50s. In all these cases, there is pronounced atheromatosis of the cerebral arteries. It is very easy to assume that the subcortical wasting of the nerve fibers is caused by the nutritional impairments caused in turn by the arteriosclerosis. In more advanced old age, too, we find this wasting of the white matter restricted to isolated parts of the brain in cases of severe senile dementia, as I have been able to assure myself only recently. A postmortem examination was performed following the death of a 74-year-old man who had been very highly gifted intellectually and had performed his very responsible work until 2 years before, when he died of rapidly progressing mental deterioration characterized by paraphasic features. Pathologically, high-grade wasting of the white matter was found throughout the region of the occipital and temporal lobes; as a result, the posterior and inferior horns were drastically expanded and the ependyma of both were grossly thickened.

There is another group of cases closely related to the arteriosclerotic process, which I classify under the general name of "arteriosclerotic brain degeneration." As this can lead to confusion with paresis in both its anatomic and clinical aspects, I feel justified in presenting it herein. At this point, I only want to attempt a brief review of its characteristic anatomic features, leaving the clinical characteristics until later in this report.

On postmortem examination of the body organs, we find extensive arteriosclerotic processes on the great vascular trunks, on the coronary arteries of the heart, and on the renal vessels, with atrophy of the renal parenchyma. The myocardium is heavily atrophied and subject to fatty degeneration. The great vessels in the brain usually show pronounced arteriosclerotic alterations, although cases are encountered in which these changes are sharply pronounced in the body arteries, while the internal carotid artery and the basilar artery, like the main branches of these vessels, are affected only relatively slightly. The brain is mostly markedly edematous; it shows a substantial weight reduction and is poorly supplied with blood. The vascular lumina are generally markedly expanded. In the immediate vicinity of the vessels, the brain substance can be seen macroscopically to be discolored, appearing light gray to reddish brown, and slightly depressed at many points of the cortex and the white matter. In the areas of the basal ganglia and the inner capsule, in particular, there is a definite cribriform state. The cortex is pale gray, indistinct, and not very thinned; the layering is unclear; the hemispheric white matter is a dirty white and grayish white in parts; and the large bundles of fibers in the inner capsule and the brain stem show this dirty gray discoloration most clearly. The brain ventricles are markedly expanded; granular ependymitis is occasionally found in the fourth and in the lateral ventricles.

Microscopic examination of the fresh brain discloses extensive degenerative processes—simple atrophic degeneration or fatty degeneration—on the small arterial and venous vessels in both the cortex and medulla, in some cases, and (in the larger arteries) pronounced partial thickening of the inner and middle vascular membranes, the nuclei of which are distinctly increased, in other cases. The lumen is correspondingly narrowed. At many points in the vascular sheath, there is an abundance of amorphous, scaly, and crystalline blood pigment as well as many lymphoid and epithelial elements. In the immediate vicinity of the vessels, too, we find blood residues as well as granular detritus, granular balls (some of them containing pigment), myelin scales, corpora amylacea, and (in the cortex) nerve cells and glial cells in the process of disintegration. Examination of the cortex of a hardened brain shows that the myelinated nerve fibers, both those in the superficial zonal layer and those in the medullary lamina and in the radial bundles, are distinctly reduced in number. (Precisely these cases lend themselves to examination by Marchi's method to determine the extent of the degenerative process and which nerve fibers are subject to the destructive process.) Degenerative atrophic processes can also easily be detected on the nerve cells in the cerebral cortex.

Herein you have a rough outline of the picture of the degeneration of the cerebral substance caused by vascular disease. We must now ask to what extent arteriosclerotic brain degeneration can be confused with general paresis. It must first be stressed that the presence of extensive arteriosclerotic changes of the arteries in the body and/or in the brain can also be observed in cases of typical paresis. The autopsy findings referred to above include those recorded in 22 cases in which severe generalized atheroma was present. These cases include eight in which the 40th year of life had not been reached (two patients had not yet reached the age of 31 years at the time of death). There were nine cases in which death had occurred between the ages of 40 and 45 years, three in which death occurred between the ages of 46 and 50 years, and two in which death occurred between the ages of 50 and 55 years. We can conclude from this that atheromatosis is not only a relatively frequent concomitant condition (a cause?) of the paretic disease process but it also occurs in more youthful paretics in whom senile involution cannot yet play any role in the process.

It will not be a mistake in these cases if we assume a causal connection between the premature development of arteriosclerosis and the syphilitic infection in the case history. As can be seen from my observations, arteriosclerosis is encountered both as an autopsy finding in typical paresis and in arteriosclerotic degeneration. Furthermore, as the macroscopic autopsy findings can be very similar in the two conditions, it will not always be possible for us to make the differential diagnosis based on the anatomic examination findings with an adequate degree of certainty. Nonetheless, it will presumably be possible to assign the patients with progressive intellectual deterioration who do not become ill until their late 40s or early 50s and who are characterized anatomically by the criteria of minute necrotic foci of the cerebral substance around the arteriosclerotic vessels or of miliary apoplexies to the group classifiable under arteriosclerotic brain deterioration and to distinguish them from those patients with paresis. If the clinical picture just described is also accompanied by rather large hemorrhagic foci, it is even easier to distinguish it from paresis.

The clinical picture discussed later in this report is of more decisive importance. So many of its features deviate from those of typical progressive paresis that making arteriosclerotic brain degeneration into a main classification heading in its own right is probably justified.

The second procedure that can be followed to discriminate paresis from diseases with similar manifestations is via the causative explanation for the nomenclature used for these conditions. It is probably no longer contested that the paretic disease process has to be regarded as the sequela of a functional overexertion of the central nervous system, particularly of the cerebral cortex. The threshold at which the average performance capacity of an individual is exceeded is obviously extremely variable. Very different factors are involved in the precipitation of organic brain disease against the background of functional overexertion.

The first factor to be considered, as all the more recent studies have shown, is syphilis. We shall have to assume that pathologic products of the syphilitic poison exert chemical effects that bring about changes in the substance of the nerves. Whether this chemical alteration alone can lead to the extensive degenerative changes in the nerve fibers and nerve cells that characterize the paretic disease process or whether it damages the affected tissue only insofar as it makes the nerve substance less resistant to other noxious influences acting on it must be regarded as an unanswered question. I lean toward the latter view and still believe that the syphilitic infection must be followed by other noxious influences if paresis is to develop. With this interpretation, we shall be able to regard syphilis only as an indirect disease agent when the whole is considered from the aspect of origin.

Accordingly, in doubtful cases in which the diagnosis of paresis cannot be made with certainty from the clinical symptoms, it cannot be concluded, based on a note of earlier syphilitic infection in the case history, that the question of the diagnosis is resolved in favor of paresis. For it is precisely the functional and organic brain diseases whose symptoms resemble paresis that not infrequently develop in individuals who have also suffered generalized or localized tissue damage as the result of an earlier syphilitic infection. Syphilitic neurasthenia with syphilitic hypochondria, for example, is a very common clinical picture. The arteriosclerotic disease process has also arisen against the background of syphilitic infection in some cases, and the discrimination of arteriosclerotic disease of the central nervous system from the paretic disease process is by no means made easier by this consideration of the cause.

The same problem—perhaps in an even more pronounced form—is encountered in the discrimination of paresis from cerebral syphilis in the strict sense of the term. In the separation of these two pathologic conditions, the method to determine the cause can only gain a hold if syphilis is definitely present, insofar as we must strive to differentiate the specific, ie, gummous, processes more precisely from the sequelae of syphilis, the indirect tissue damage of a nonspecific nature. Viewed theoretically, the task appears to be rather easy: all diseases of the central nervous system, and specifically of the brain, that directly follow the syphilitic infection are to be assigned to the specific processes, while all late forms, ie, all diseases of the central nervous system that lag behind the specific syphilitic manifestations, so to speak, belong to the group of illnesses that are brought about indirectly by syphilis (tabes and paresis). In practice, however, everything turns out quite differently: on the one hand, it is shown beyond all doubt by clinical and anatomic examination that simultaneously with the most varied syphilitic eruptions (diseased states of skin, mucous membranes, and bones) the postsyphilitic degenerative process can also start to develop. To remain with paresis, enough cases have been reported in which the entire course of the illness has only taken 2 to 3 years from the syphilitic infection to the fatal outcome and in which specific manifestations of illness have been present in an unremitting sequence, in parallel with severe and very pronounced brain symptoms. The anatomic examination then discloses the characteristic features of progressive paresis, while consideration of the origin suggested that a specific disease process was much more probable. In cases with such a fulminant course, then, the diagnosis cannot be made with certainty from the clinical course of the illness. Conversely, we encounter patients with quite pronounced cerebral syphilis in whom the syphilis had existed for years without any obvious manifestations of disorders before the onset of a new episode of the illness.

We see, then, that consideration of the temporal sequence of the manifestations of the illness is not of much help in the differential diagnosis between cerebral syphilis and progressive paralysis, even after establishment of the common causative factor.

Discussions of the other causes of progressive paresis will not yield success in finding a crucial feature, either among the predisposing moments or among those directly involved in the causation of the illness, that can be regarded as the determining factor allowing the diagnosis to be made in doubtful cases. Heritability, which, contrary to earlier assumptions, plays an important role in paralysis, alcoholism, and the plurality of noxious influences common to all persons in civilized societies, owing to present-day social circumstances, to the existentially harder struggle, and to the exaggeratedly hasty way of life, do not cause exclusively one or the other functional or organic psychic illness. On the contrary, we have to say that the same causative factors can most certainly lead to different kinds of disease processes, depending on the predisposition and the constitution of the person affected.

The present status of our knowledge of causative relationships allows no other assumption but that in the area of neurologic diseases, the localization and extent of a disease process will be determined primarily by the degree of anatomic and physiologic development of some segment of the nervous system in the determination of the level of resistance that precisely this segment possesses against pathologic influences. Compared with this level of anatomic and functional development determined by predisposition and "training," the specific localized mechanism of action of particular noxious influences can be assumed to play a less important role.

I should like to include just one example at this point to illustrate these reflections, which I have advisedly kept on a general plane. An irregular, dissolute way of life that is also overburdened by physical or intellectual work leads in one case (with or without syphilitic infection or chronic alcohol abuse) to the typical clinical picture of organic attrition of the central nervous system, that is, to paresis. In another case, the only consequence is functional attrition with an impaired equilibrium, that is, neurasthenia. In a third case, the influence of these noxious influences [*editor's note: original word used was "noxae"*] makes itself felt primarily in organic disease of the vascular system, in those endarteritic and mesarteritic disease processes that are the cause of far-reaching functional impairments and anatomic alterations in a very wide variety of organs. Here, we see that, while the nature of the noxious influences is the same, it is the particular anatomic and functional constitution of the individual organ systems that determines the particular location and extent of the disease processes.

Here I begin the third part of my discussion, in which it is my intention to discuss the differential diagnostic aspects offered by the clinical course. I should need to speak at unreasonable length if I were to present the entire, exceptionally varied psychic and somatic signs and symptoms of paresis at this point, with reference to the value I assign to them for the process of diagnosis. It is made easier for me to evade this task, insofar as I am addressing a gathering of fellow specialists who are familiar with these clinical facts. I can therefore restrict myself to drawing attention to the mistakes that can be made in diagnosis: on the one hand, those that easily come up in the early stages of paresis, and on the other hand, those that can be made in the group of so-called atypical cases of paresis as a consequence of confusion with clinically related organic brain diseases. I shall begin with the form of illness that I have referred to earlier, in the section dealing with anatomy, as arteriosclerotic brain degeneration.

However uniform and unequivocal the anatomic findings may be, the clinical picture can vary extremely widely both in the intensity of the manifestations of illness and in the sequence of their appearance. I want now to attempt to divide these different types of clinical pictures into two groups. It will be best if I append the description of the first to the report of a case that was the subject of some controversy over whether it should be classified as progressive paresis, even among physicians qualified in our speciality.

The patient was a man in his early 50s who was physically inadequately developed with a delicate bone structure and underdeveloped muscles, soft, flabby adipose tissue, and slack skin. Those arteries that could be palpated were markedly twisted and rigid, the action of the heart was weak and arrhythmic, and the urine was increased in volume and contained traces of protein.

Intellectually, the following findings were observed: a loss of intellectual freshness and liveliness, progressing slowly, almost imperceptibly, in the course of the preceding years; temporarily, in individual situations, no loss of judgment or consistency in carrying out a plan once it was decided, although he had previously been highly developed intellectually and perspicacious. However, these times of high performance were followed by periods of extreme physical and intellectual sluggishness varying in duration, with apathetic, intellectually sluggish behavior and a pathologic tendency to sleep and with a sharply distinct lack of capacity for any intellectual effort. His judgment became blurred, his memory was impaired, in some areas severely, and the patient was weak willed, indecisive, and, at these times, ethically wanting. His mental impulses were confined to the satisfaction of base, sensual needs, which refer to culinary or sexual pleasures. Most aesthetic and ethical judgment left the patient during the satisfaction of these wishes; he was extravagant, cynical, lascivious, emotionally labile, and abnormally excitable emotionally.

The periods of capability became increasingly shorter and were gradually restricted to only a few hours of the day, eventually ceasing altogether. However, even in later stages of the course of the illness, an unanticipated, almost lightning flash of his earlier intellectual powers would be observed—to everyone's amazement—showing that while the energy needed for intellectual performance was severely impaired, the individual elements of the earlier intellectual assets were not completely lost and could on occasion be brought together to provide a continuous train of thought.

The course of the illness was also characterized by attacks of giddiness, momentary episodes of unconsciousness, lengthy periods of clouded consciousness, incoherence, loss of orientation, hallucinatory agitation, and passing manifestations of paralysis affecting isolated segments of the body musculature (eg, impaired ability to swallow and to speak, hemiparesis, and monoparesis). The patient's strength was progressively lost; the fatal outcome was precipitated by an intercurrent illness (pneumonia). [*Editor's note: The third part of the article, "Continuation, Conclusion."*]

In the above sketch of the course of illness, I have taken, as a basis, a case that ended in death within 2 years as a result of episodes of illness following each other in quick succession. An essential point I should like to stress is that despite this rapid progression of intellectual wasting, the intermittent course of the condition was unmistakable up to the last months of the patient's life and as a result of these—later admittedly short-term—remissions, the signs of intellectual loss seemed substantially less pronounced than suggested by his behavior the rest of the time. We can conclude from this that during the course of the illness, numerous processes of fatigue and inhibition (fluctuations in brain pressure, manifestations of compression, and passing nutritional disturbances) supplemented the manifestations of deficiency. If these sometimes temporarily disappear, the differential diagnosis against progressive paresis is ensured. The latter, as is known, also involves remission periods varying in duration. They do not, however, start so suddenly and unexpectedly as in arteriosclerotic brain degeneration. Rather, they represent a longer or shorter stagnation of the disease, during which a relative recovery of the intellect proceeds only slowly, and, even at the most pronounced point of the remission, the impairment of intellectual performance conditioned by the previous episode of illness remains clearly recognizable as an irremediable defect. The patients, I suppose, gradually learn to live with their remaining intellectual abilities and are capable of simple thought processes; the permanent losses, nonetheless, exclude the possibility to accomplish complicated intellectual performances comparable with those of the time when they were still in good health.

This difference between the two illnesses is very probably conditioned by the different natures of the anatomic processes in each: general paresis has a diffuse onset and, at least in the cases with a chronic course, is primarily an atrophic degenerative type of brain disease, which does not lead to signs of illness in the area of intellect until a large number of the finest associative connections have already been irrevocably lost. Arteriosclerotic brain degeneration, in contrast, starts in a focal way and most probably leads to only circumscribed areas of degeneration of the different types of fiber systems of the cerebrum.

Those cases of illness that belong, judging by their clinical course, to the second group, show the following characteristic features: the onset of illness is the same as in the first group, but the course of the illness is far more protracted, as there are remissions lasting for some months or even years between the individual episodes of illness, which are entirely similar in type to those encountered in the first group.

The patients then exhibit a clinical picture that includes abundant traits related to both postapoplectic dementia and dementia paralytica. It is characteristic for these stages of relative stagnation of the disease that the intellectual abilities are reduced. Of course, this appears in quite different ways, depending on the point at which such a resting phase happens to be observed. Quite a different stock of intellectual assets will be found in such a patient if he is examined in the early stages than if an intelligence test of this kind is performed after a long disease duration with numerous episodes of illness. In general, it is possible to say that in these cases with a protracted course, in which the individual acute and subacute episodes of illness can be far apart, the manifestations of the losses sustained are much more obvious than in the first group.

It is primarily the memory that is impaired, in a way analogous to that with which we are familiar from other acquired states of mental weakness. Facts from the past, before the onset of the disease process, can be recalled relatively well, although closer examination can disclose all sorts of gaps and errors even in memories from this period. The capacity for remembering figures and names is particularly badly compromised. The memory defect is far more obvious in its bearing on the immediate past. Even important events have been erased from the memory after a few days.

In later stages, the patients are operating in the present as though they were persons for whom there are only new and unaccustomed experiences every day. They therefore find it difficult to manage in these constantly changing living conditions. Because the patients' attention, that is, the ability to absorb and retain sensory impressions, is also profoundly impaired, their efforts are frequently in vain. The patients are disorientated and confused about their surroundings, identifying places and persons with others remembered from the time before they were ill.

The patients' weak judgment is very obvious once many memories are lost and the associative links between the remaining ones are deeply impaired. This weakness varies, of course, with the degree of impairment suffered by the aforementioned components of intellectual performance.

In many cases, a credulous or light-hearted attitude toward important decisions, presenting a gross contrast to an earlier keen judgment, is the first obvious sign of the intellectual defect, when a remission period occurs early in the disease after only a few episodes of illness. The mental impoverishment in the area of judgmental associations is much more pronounced in the later stages. Any business arrangements are completely obscure and nonsensical and fortunately are nipped in the bud, because it would be impossible to implement them. However, even the less responsible, ordinary arrangements that have to be made in everyday life are seriously affected. The patients are untidy, negligent, and indifferent to the laws of decency and propriety. The mental impoverishment ultimately leads to the complete absence of thought and judgment, typified outwardly by apathetic brooding. Any oral utterance is restricted to repetition of isolated, completely unconnected words.

The patients' mood in the later stages is generally dull and indifferent, as the sensory and intellectual nuances of feeling have been destroyed for the most part, in keeping with the general disintegration of the intellect. In the earlier stages, in contrast, pathologic accentuations of affect are almost a regular part of the clinical picture. Cheerful, angry, and anxious affect occur in any order, in a similar way to that seen in paresis. However, the euphoria typically seen in paresis is absent, particularly in the initial stages. Even in the later course, however, the patients very frequently still have a good insight into their illness and accordingly have a mournful, occasionally even despairing mood that is quite in keeping with the patients' awareness of the illness.

The many points of contact with the course of paresis with dementia are unmistakable, but the physical symptoms will make it considerably easier to draw a distinction. It is true that the motor impairment is the same in many points in the two conditions: central paralysis of the facial nerve, of the hypoglossal nerve, and of the musculature of the trunk and extremities is also a part of the clinical picture of arteriosclerotic brain degeneration. In the earlier stages, these are mainly monoparetic and hemiparetic manifestations, while later a general enfeeblement of corticomotor performance is present, admittedly with impairments on one side of the body predominating. During voluntary movements, there is usually an intention tremor—more or less pronounced—and ataxias are also observed, particularly following episodes of illness.

In contrast, in the unmixed cases, the pupillary reaction is not impaired, and the paralysis of the outer ocular muscles or the speech disturbance that are characteristic of paresis are not present. Speech becomes slow and more awkward and clumsy, but the hesitation, stumbling over syllables, slurring, and transposition of individual consonants or syllables are lacking. Aphasias can also be observed intermittently, again in the course of or subsequent to the paroxysmal processes of the disease. A closer analysis of these reveals that they are motor and sensory disturbances, but mostly so-called transcortical (paraphasic) aphasic disturbances. Optic aphasia (word blindness) is also intermittently observed.

The course of the illness in these cases is occasionally also characterized by the manifestations of a pronounced apoplectic insult, with lasting symptoms of motor deficiency on one side of the body during an episode of the illness. In this case, a superficial consideration will hardly allow discrimination of the condition from the secondary demented states following focal illness of the brain. Closer inspection, particularly consideration of the overall development, will then make the diagnosis of arteriosclerotic brain degeneration possible.

In fact, however, it should not be denied that from the aspect of pathogenesis, the focal illnesses based on arteriosclerosis (hemorrhages, embolic, and thrombotic softening) have equal weight with the form of illness described herein as generalized arteriosclerotic brain degeneration. The anatomic and clinical differences stem from the multiple or even miliary character of the foci of softening and the extensive degeneration of the cortex and white matter linked to this process. This association also explains why mixed forms are quite common, as the miliary foci are joined by larger ones with stable manifestations of deficiency.

Because this arteriosclerotic degeneration almost always begins on the borderline between the prime of life and the onset of senile involution (in the early 50s), its discrimination from simple senile dementia is also problematic, especially in the early stages. Arteriosclerotic degeneration can be differentiated by the initially relatively fast progress of the disease and the intermittent course from conventional senile dementia. I am convinced that the majority of the controversial cases in which the diagnosis oscillates between paresis and so-called premature senility [*editor's note: original term used was "senium praecox"*] belong in this category.

I should like to stress again that the arteriosclerotic disease of the kidney that is frequently present can be an important factor in determining the diagnosis. It is therefore essential to insist on a investigation. The full, hard, tense nature of the pulse will also help to ensure the diagnosis. Pronounced hypertrophy of the heart is not always present, even when kidney disease exists; the reason for this mostly has to do with the brown atrophy and fatty degeneration of the myocardium that are detectable on autopsy.

During the same period of life, we encounter cases of pronounced mental disintegration that cannot be classified as paresis in either anatomic or clinical terms. I should like to classify cases of this kind under the heading "simple presenile dementia."

This condition usually affects persons in whom intellectual development has remained at a relatively low level. While such people cannot be described as feeble minded in the usual sense of the term, such individuals do show a certain imperfection in mental development, which is characterized by an inability to see tasks through to their completion, so that they fail financially, and in some cases morally, at every turn and by the fact that these people are prematurely defeated among the everlasting toil and trouble of existence. Often, such people are only in their late 40s or early 50s when their keenness of judgment—which is hardly exceptional anyway—is restricted further, to such an extent that it is obvious even to someone who is not particularly close. Their creative ability wanes. The man who was always restless and busy becomes apathetic, weak willed, and rather indifferent; considerable gaps in memory become obvious; the posture is slack; the speech is monotonous and tremulous; and the movements of the extremities are limp and accompanied by a slight static and ataxic tremor. Some gross commercial failure—for example, the inability to continue keeping accounts, obvious errors in the administration of the petty cash, or nonsensical, pointless orders—leads to a storm and compels these persons to renounce even the last remnants of apparent work. Easy mechanical occupations or, in the case of educated persons, the study of books and periodicals, but above all their anxiety over food and drink, fill up their day. They need constant supervision, because in their pathologic overestimation of their own abilities, especially under the influence of slight emotional excitement, they independently act in an inexpedient manner or, because of their severely weak judgment and will, can be led into dangerous and even illegal actions by other people.

What these patients have in common with those affected by paresis is mental disintegration with the loss of finer aesthetic and ethical ideas. At the peak of the illness, they overlap with the clinical picture of simple paretic dementia. Nonetheless, they differ from full-blown paresis in that the typical somatic signs of illness are absent; the pupillary reaction may be rather more sluggish, but I have never observed an actually nonreactive pupil in such cases of presenile dementia. The speech is tremulous and often rather nasal and less clear; the typical hesitation or falling over syllables is absent in these cases. The facial area is weakly innervated, but there are no clearly defined signs of paralysis, such as those that are peculiar to fully developed paresis. The knee phenomena [*editor's note: patellar tendon reflexes*] are always overactive. The further course also differentiates these patients from those with typical paresis, as the progressive character is hardly pronounced; the patients remain in this same state of mental dullness and physical weakness for many years, until some intercurrent illness finally brings about death. It is not rare for such patients to die of internal hemorrhagic pachymeningitis of acute or subacute onset.

There is one causative, clinical aspect that is of decisive importance for the differential diagnosis and that can easily be established by a careful elicitation of the history. In these cases, varying degrees of inhibition of development are encountered in the intellectual sector. The action of a particular noxious influence, such as intellectual overexertion, alcoholism, and syphilis, is by no means necessary for this mentally defective state to come about; such noxious influences [*editor's note: "noxae"*], however, would presumably exacerbate the central nervous system's lack of resistance and accelerate the onset of the intellectual degeneration.

Mixed forms are encountered here as well, as true manifestations of paretic illness may be added to the clinical picture described above. In such cases, we find changes brought about by the paresis on anatomic examination, while in unadulterated presenile dementia, examination reveals only the anatomic features of the elderly brain.

An additional task still awaiting a solution is the discrimination of the cases characterized above, based on their anatomic features, as chronic progressive subcortical encephalitis, from progressive paralysis. I want to illustrate this, too, with a case report.

A factory owner in his late 40s, who had been infected with syphilis 26 years earlier, became ill after suffering from long-standing sciatic pain 12 years before and after also experiencing ptyalism, reduced sight in the right eye (disseminated choroiditis), giddiness that had begun some years earlier, severe left-sided headache, paresthesias (tingling, feelings of "pins and needles," and numbness) in the right arm and right leg, and impairment of the finer coordinated movements of the right hand and fingers, which became manifest in uncertainty, clumsiness, and more rapid fatigability during writing and dressing and undressing. No reduced perception of touch or pain was detectable objectively in the affected extremities, nor did the patient's perceptions of pressure, position, or touch show any obvious attenuation. The coarse motor strength on the right side was also unimpaired. In addition, the patient complained of difficulty with his speech, specifically that he was often unable to express his thoughts precisely because the words escaped him. He often had to have recourse to circumlocutions, because the most appropriate word did not come to mind. No difficulty with articulation or paralytic speech impairment was present. At the same time, there were sleeplessness; an unhappy, hypochondriacal mood; and fear of becoming mentally ill. It was particularly distressing for him that sometimes when he was in the middle of a conversation not only would words fail him but his memory would break down completely. When he was relating his experiences in the German-French war, for example, he would suddenly have no memory of where he had been on a given occasion or of what he had done and seen. He was able to give a good, coherent account of anything he had just experienced and of his own circumstances and those of his family, and he was fully conscious of his condition. It was striking that he found arithmetic calculations involving numbers with several digits difficult. Antisyphilitic treatments brought about a relative recovery—the headaches disappeared, as did the disturbances in the extremities, and the aphasic speech impairment diminished in severity, so that the patient's speech failed briefly only in times of physical and mental fatigue. He went about his business as before, but he did not have his earlier mental freshness; not only did he tire more quickly, but his work was also inferior in quality, as his brother and business partner were soon able to observe. The aphasic disturbances had not been substantially influenced by the antisyphilitic treatment. The reduction in intellectual capacity became more severe during subsequent years. The patient became more forgetful, especially as far as the immediate past was concerned. His judgment in business decisions dwindled increasingly, while the speech impairment progressed and became distinctly paraphasic. His affect had become characterized by easy excitability with tendencies toward fits of anger and anxious, tearful agitation. When he was 53 years of age, he had to be admitted to an institution, as he had started to have more violent fits of agitation. The patient would get up during the night to look for burglars, would talk excitedly, and, in an incomprehensible and disconnected manner, would attempt to run into the street and, if prevented from carrying out his intentions, fly into a passionate rage.

The following findings were recorded on admission on February 22, 1889, and in the later case history: scar on the right tonsil and left palatal velum; scar to the left of the frenulum preputii; no swollen glands; slight periosteal deposits on both tibiae; markedly winding arteries that were more rigid on the right side than on the left side; a pulse of 94 beats per minute; weak, pure heart sounds; normal cardiac dullness; and urinary acid that was free of protein. Pupils were average in width and were equal, and all pupillary reactions were perfectly prompt; eye movements were unrestricted; ocular fissures were equal; the left side of face and mouth were perceptibly more heavily innervated than the right side, which was obvious at rest, during activity, and in the adoption of facial expression; irregular blowing out of the cheeks—sometimes more pronounced on the right, sometimes on the left; obvious deviation of the tongue to the left side when protruded, and the tongue could also be easily protruded from the corner of the mouth; no tremor; motor strength in the upper extremities that was only slightly reduced on both sides; hand grip measured with a dynamometer on the right (75, 77, 95, 100, and 86) and left (55, 80, 78, 70, and 80); very fine manual tremor; finer arm and hand movements, such as buttoning and unbuttoning, well maintained on both sides; motor strength in lower extremities reduced on both sides, decidedly more severely on right than on left; normal gait; and absent Romberg's sign.

The patient's speech was completely disconnected and incomprehensible. He would string words together in an absolutely meaningless way. When he was shown a spoon, he called it a "school," then shook his head, obviously trying to find the right word. When "spoon" was said to him, he agreed at once and murmured the word spoon several times. The ability to repeat proved to be intact, and verbal comprehension was seen in easy exercises to be relatively well preserved. A series of objects was shown to the patient, and he was asked to give one of them, specified by name, to the physician. In most cases, he selected the correct object; occasionally, for example, when the word "pencil" was specified, he looked at the physician in amazement and did not point to the pencil right in front of him. During one attempt, he confused pencil and pen. When asked to show his tongue or to hold out his left or right hand, he was able to do so correctly.

Physician: "Where is my ring?" *Patient:* "My—your—ring?" (looks at his hand). *Physician:* "Point to my ring!" Patient draws a ring in the air with his finger. *Physician:* "Point to my ring on my left hand!" Patient looks at his left hand.

The patient's verbal designation of objects held up to him was variable, as seen by the following exchange: A clock is held up. "That is . . . well, I really don't know—Erfurt—in Erfurt." A hat is held up. "A hat." A ring is held up. "That's a hat too." A glove is held up.

That's a dog—shoe—paltry." An inkwell is held up. "Loaf of bread." *Physician:* "No it's not bread." *Patient:* "Nay, the blue thing . . ." (The inkwell looks blue.) A pen is held up. "Pen." A purse is held up. "That's—I don't know—200 and some. That's nice isn't it." Even when touching the purse, he does not come upon the correct word for it. A thaler (a coin) is held up. "A thaler." A one-mark piece is held up. "That's a 20—a silver penny, no, two." A cuff is held up. "Cuff" (quickly). He was not able to come up with the word for key but made the correct motion of unlocking.

When objects were put into his hand for him to examine them by touch while keeping his eyes closed, he identified them correctly and incorrectly, using paraphasic names in approximately the same proportions as on sight of them. It was obvious that his ability to identify objects from the way they feel was intact, because, while he sometimes gave identified an object incorrectly, when it was put into his other hand, he remarked correctly, "That's the same thing."

When reading, the patient skipped over words and phrases and rearranged others in such a way as to sound fantastic. For example, instead of "We should have preferred them to elect a Frenchman, one of our brothers in the faith, but they have followed their hearts and we accept this" (large print in newspaper), he read the following: "We should have had a Negro brother in the faith—it is a repulsive story—and their heart's decision up to early us." Further mistakes arose from the fact that the patient often wandered from one line to the next.

Although he was able to understand the request "Give me your left hand" correctly if he took his time, he did not comply with it. He consistently read isolated letters correctly when they were written for him. The patient was usually able to read numbers with three digits correctly, but they were displaced and confused when there were four or more.

The patient's writing ability was impaired. He often wrote down his own name spontaneously and correctly, but sometimes individual letters were omitted or inappropriate ones were inserted. From dictation, he wrote "Schnurrbart" (moustache), for example, as "Schurpaupa" and then, at the next attempt, as "Schutt . . . ," with a few completely illegible and incomprehensible letters. The patient wrote the word "Licht" (light) correctly from dictation. The ability to copy was also severely impaired. Instead of "Schnurrbart," he wrote "Nachbar Baupahrer," then "Nannhbarbobiterin,", and, finally, completely illegible signs.

Sensitivity to pain was retained consistently; sensitivity to touch could not be precisely tested. The smell of Peru balsam and NH_3 was apparently perceived on both sides. Words spoken quietly from half a yard away were heard with both the right and the left ears. On hearing the ticking of a clock while keeping his eyes closed, the patient concluded promptly, "That's a clock." No great impairment of the sense of taste could be demonstrated.

Facial expression was quite intelligent, although a little perplexed and surprised. If anyone smiled at him or put out his hand, he smiled cordially and shook the proferred hand quite politely, making a correct half-bow. Sometimes he clasped his hands together, and his face assumed a piteous expression. He rolled his eyes upward and tried to make something clear to the physician, but the paraphasia was so severe that it was impossible to understand what he wanted to say.

On February 24, 1889, the patient was very restless during the night, was out of bed a great deal, and was anxious to reach the door. The following dialogue took place the next day: *Physician:* "Who am I?" *Patient:* "You're the . . ." *Physician:* "Vicar?" *Patient:* "No." *Physician:* "Doctor?" *Patient:* "Yes."

The patient was often tearful and anxious, even during the daytime, and when asked a question, he frequently repeated some word in it, as if automatically. On February 28, 1889, he sang the melody to "Kommt ein Vogel geflogen" (without the words) right through, quickly and without any mistakes. At the end he said "I've had a lot to do with music."

On March 3, 1889, the patient showed increased restlessness. Only occasionally did he sit still for a few minutes; otherwise, he kept walking about everywhere with long strides as though looking for something. When anyone tried to stop him, he said, "Oh my God, just let me go. All the day I'm—just be so kind once again."

On March 4, 1889, the patient was quizzed with the following math problems: 3×2? *Patient:* "7.' 3×3? *Patient:* "9." 7×8? *Patient:* "3×3, $3 \times 3 = 9$."

On March 7, 1889, it was established that the patient was no longer able to play the piano. On March 12, 1889, when the patient was scolded violently, he sometimes used words correctly that he otherwise uttered in inappropriate context. On March 15, 1889, there was no constant pattern in the misuse of words. The patient very frequently used conventional phrases instead of saying what he wanted to say. When he read over what he had written down during a spell of paraphasia, he noticed his own spelling mistakes. On March 21, 1889, the patient put on his clothes in the wrong order.

On April 7, 1889, the patient sometimes went up to one of the other patients and paid a compliment. His bearing often gave the impression that he thought that he was at a social gathering. On May 1, 1889, it was noted that now and then he had a slight list to the right. On June 1, 1889, the patient was quite often noted to be very noisy during the night. On July 12, 1889, the patient probably recognized a relative correctly, judging from his facial expression, but he addressed him by the wrong name.

On March 4, 1890, the patient seemed to have recognized the physician he had previously seen during a visit. On May 1, 1890, the patient had recently started to repeat words wrongly as well. He often made automatic rubbing movements with his hands against his thighs. On July 1, 1890, the patient was no longer able to write his name correctly. On April 10, 1891, the test of verbal comprehension was administered as on admission. He read "Weimarische Zeitung" as "Zeitung—Schornische" and "Amtliche Nachrichten" as "Amtlich." The patient did not read any further. When he was asked to write from dictation, he wrote down only isolated letters correctly. In spontaneous writing, he also managed only isolated letters followed by illegible lines. When copying, he wrote only the first letter correctly and then added some inappropriate ones. The patient was frequently incontinent.

On February 18, 1892, the patient suffered an epileptic fit in the morning, with an initial cry, followed by tonic-clonic movements of short duration, and then coordinated thrashing of his arms and legs. Afterward, he slept for several hours. His temperature was 37.4°C. At 2 PM, the patient vomited; at 4:30, he soiled himself.

On February 19, 1892, the patient was restless and incontinent during the night, showed no impairment of cutaneous reflexes or tendon phenomena, reacted to symmetrical pin pricks, showed innervation of right- and left-sided muscles, showed no gross impairment of sight and hearing, and exhibited a somewhat reeling gait.

On June 7, 1892, the patient experienced a second epileptic insult, which was followed by violent agitation. The patient threw himself about the bed and thrashed. On December 6, 1892, the knee-jerk reflex could no longer be elicited. The patient had a temperature of 39.2°C in the evening, accompanied by diarrhea. On January 10, 1893, the patient appeared dull, apathetic, and very weak. On March 10, 1893, direct and indirect pupillary reactions were retained on both sides. The patient was more sluggish, exhibited divergent strabismus on the left side, had moderate knee-jerk reflexes on both sides, was sensitive to pain throughout his body, no longer complied with even simple requests, no longer was able to name objects held up to him, was able to repeat "Buch" (book) and "Hut" (hat), exhibited a pronounced weight loss, had to be fed, was completely incontinent, and had a fluctuating body temperature often noted in the evenings.

On June 3, 1893, the patient remained in the decubitus position and had a temperature of 39.3°C. His respiration had slowed and his face was very flushed. On June 6, 1893, at 9 PM, the patient died. A postmortem examination was performed on June 7, 1893, at 11 AM by Professor W. Müller.

The following information was taken from the report: Spinal cord: roots white; cervical spinal cord flat; substances of all kinds extremely pale; the posterior bundles beside the raphe pale grayish yellow. Upper thoracic spinal cord: anterior bundles white; grayish red-tinged radial striation of lateral bundles almost throughout, except for the mediolateral part; posterior bundles gray. Lower thoracic spinal cord: anterior bundles white; the right lateral bundle, more than the left, reddish gray, particularly in the posterior third; posterior bundles pale reddish gray in the anterior half, yellowish gray in the posterior half; gray matter very pale. Lumbar spinal cord: flat; anterior bundles white; reddish gray striation of lateral bundles, especially toward the gray matter; posterior bundles gray; gray matter very pale; central channel unrecognizable throughout. Soft meninges: thin, except for isolated, highly insignificant opacities of the arachnoid membrane; pronounced external hydrocephalus; frontal gyri obviously narrowed, with increasing intensity from back to front; dura basalis covered with reddish yellow spots of a gelatinous substance in the anterior and medial parts of the cerebral cavity. Brain weight: 1285 g.

Only isolated, insignificant opacities were seen in basilar arteries. The lateral chambers of the brain were very considerably expanded, especially the inferior horn; the cerebrum was pale throughout; and the gray matter was rather thin in the frontal part. The white matter of the lower parietal lobe and of the upper and lateral parts of the temporal lobe was extremely wasted, especially on the left side. Expansion of the lateral ventricle accordingly affected mainly the initial sections of the posterior and inferior horns; the ependyma was markedly thickened; and there were no signs of focal disease. (The more detailed examination of the brain by means of serial sections to determine the extent of medullary fiber wasting will be discussed later in conjunction with the discussion of other relevant cases.)

After hardening of the brain in potassium dichromate, the wasting of the white matter in these parts was particularly distinct. The posterior part of the hemisphere was considerably more severely reduced in size on the left compared with the right side. In a coronal section obtained approximately through the middle of the posterior branch of the sylvian fissure and the posterior margin of the operculum, the right half of the hemisphere had a maximum width of 8.7 cm, while the width of the left half at the same point was only 7.3 cm.

The above case history can be summarized as follows: Infection with syphilis in the mid-20s; first upsets affecting the nervous system (sciatic nerve) at 40 years of age; ptyalism for 1.5 years starting at age 44 years; disseminated choroiditis at age 48 years; first signs of brain disease also at age 48 years, with those of motor aphasia and later of paraphasia being the most pronounced; paraphasia and dysgraphia, paralexia and dyslexia; increasing loss of memory, confusion, incoherence, and overexcitement, while linguistic difficulties remain almost stable; at age 56 years, two epileptic insults; increasing intellectual deterioration; at age 57 years, final disintegration of strength and, finally, death. Postmortem examination revealed slight arteriosclerosis; diffuse disease of the spinal cord; no macroscopically recognizable syphilitic infection of the cerebral arteries; no substantial leptomeningitis; severe wasting of the white matter of the parietal and temporal lobes, especially on the left side; and moderate atrophy of the cortex of the frontal lobe.

The development and the course of the illness also suggest that the disease process must have destroyed parts of the medullary fibers in the left hemisphere, specifically the following tracts: (1) between the centers for image formation and the acoustic speech center and between these and the reading and writing centers; (2) between the reading and writing centers and the acoustic speech center; and (3) between the acoustic and the motor speech centers.

In keeping with this extensive, but functionally and anatomically only fragmentary, destruction of association fibers, the aphasic symptoms are very varied and equivocal. It includes a mixture of features that are characteristic of both transcortical and intercenter tract aphasias. At this stage, of course—before precise and thorough examination of the brain—it is quite impossible to say whether it is exclusively association and interhemispheric fibers that are destroyed or whether projection fibers are also affected. Even the macroscopic findings allow the conclusion that the latter is probably true. The speech impairment would then be attributable in part to the latter explanation, and signs of an incomplete agnostic sensory aphasia and alexia could accordingly be expected to be added to the disturbances listed above. (Herein, I make use of the terms used by Ziehen in his clear and well-structured treatment of aphasia for the individual aphasic conditions ["Aphasie," in *Real Encyclopaedie*, 3rd ed].)

We can be sure that further in the course of the illness, the wasting of the nerve fibers is not confined to the regions of the brain specified above. The final intellectual disintegration suggests that innumerable tracts in the entire medulla of the hemisphere have been damaged and ultimately destroyed on both sides of the cerebrum. The involvement of the intracortical conduction fibers can also only be established by means of precise histologic examination. As seen from the sectional investigation mentioned above, the spinal cord is also affected by the degenerative processes.

I shall have to be content with this one example here. I hope to be able to give a more detailed account of this condition eventually, based on a full and accurate description of eight relevant cases. These vary in some features; the characteristics common to all and peculiar to this condition are as follows: onset of illness on the threshold of old age (early 50s) or actually in the senium (early 60s); slow development of the deterioration of the intellectual capacities, noticeable primarily in the gradually progressing difficulty in association and ultimate loss of the associative connection between particular sensory areas in the cortex or motor segments (as in the case described above); hemiamblyopia or hemianopsia; and hemiparesis with loss of perception of pressure, position, and touch. At the peak of the illness, these symptoms of deficiency are quite stable and are associated with a generalized and unremittingly progressive reduction of intellectual ability; the patient's mental operations are later restricted to an extremely small scope. All more ambitious intellectual interests start to fade and eventually a state of severe intellectual devastation develops, in which the patient is devoid of any independent will power and either lies in bed in an apathetic, glazed manner with a completely stupefied facial expression or, if they have been washed and dressed, walk about the room without aim or purpose. If I may be allowed to make a comparison at this point, when they reach this terminal stage, the patients are like the decerebrated animals used by Goltz in his experiments.

Apoplectiform fits occur during the course of the illness, corresponding in their mildest form to attacks of giddiness and fainting and characterized in more complicated forms by unconsciousness varying in duration and by paralysis on one side of the body with corticomotor irritation (clonic twitching) in the paretic muscles and fully developed manifestations of aphasia (motor and sensory aphasia, dyslexia, optic agnosia, word blindness, etc). Full-blown epileptic fits are occasionally also seen as part of the clinical picture. Furthermore, prolonged phases of psychic agitation develop, sometimes lasting weeks or months, during which the patients show increased motor agitation (restless rushing about and loud shouting), sleeplessness, choleric irritability, complete incoherence, confusion with acceleration of the imagination, and innumerable misperceptions. The course of the illness is extremely protracted (10 years or longer) in the majority of cases. There is often a remission lasting for some years; the illness is then wrongly interpreted as a focal affliction (softening, hemorrhage, or embolism) of particular regions of the cortex with subsequent dementia, as a consequence of the localized and stable deficiencies. Death occurs during an apoplectiform fit, as a result of some intercurrent illness, or during the terminal stage of dementia as a direct result of decubitus, marasmus, and cardiac arrest.

These cases differ from paresis (1) in the stable manifestations of deficiencies; (2) by the peculiar development of the intellectual defect (patchy loss of memory, difficulties with connections, and breakage of connections between the individual corticomotor and corticosensory centers); (3) in the characteristic course (the average duration of illness is much longer than in typical paresis); and (4) in the postmortem findings.

Clinical differentiation from arteriosclerotic brain degeneration is possible based on the following: in the former condition, the focal manifestation of a transitory nature and the deficiency symptoms indicate a diffuse affliction of the brain from the very beginning, while in the latter the disease process initially has a circumscribed character confined to particular regions of the hemisphere, so that isolated deficiency syndromes of the type described dominate the clinical picture from the start. Given the close relationship between the anatomic processes, there are doubtless also intermediate forms in which the stable deficiency symptoms that are restricted to particular sensory or motor functions are less pronounced and relatively inconspicuous compared with the general intellectual defect precipitated by the generalized nerve fiber wasting and/or loss of associative connections. Postapoplectic dementia borders on this form of illness. The clinical picture differs from that of the first-named condition both in the development (the acute onset of illness with fully developed apoplectic insult) and in the course (stable character of the clinical picture with regard to both the localized manifestations of deficiency and the intellectual defect). In particular, however, the postmortem findings are quite different. It is not difficult to differentiate this postapoplectic dementia from typical paresis in the majority of cases. The development and the particular form of the intellectual defect, the manifold changes, and the peculiar association of somatic and psychic manifestations of illness, like the course, are sufficiently characteristic in general paresis to guard against such confusion.

Syphilitic focal disease, in contrast, quite often is difficult to diagnose. Pronounced focal symptoms, eg, motor aphasia, hemiparesis, and hemianopsia, varying in duration are known to occur in both disease processes, although they are completely different anatomically. Discrimination between the two is especially difficult in the initial stages, when the intellectual defect peculiar to paresis is not yet pronounced. Subsequently, it is almost impossible to differentiate paresis with an acute onset and fulminant course from the syphilitic focal disease that is associated with extensive gummous meningitic processes and has led to severe generalized signs and symptoms (prolonged spells of profound inhibition of thought or incoherence, hallucinatory agitation, etc). The differential diagnosis is more difficult, because certain somatic manifestations of response and of deficiency are characteristic of both conditions—paralysis of individual external optic muscles, oral branch of the facial nerve and the tongue, hemipareses of the extremities, and clonic twitching in the paretic muscles. If the internal ocular muscles are intact, so that the pupillary reaction is not impaired, or if only a unilateral pupillary impairment is present—with simultaneous disturbance of the reaction to light and the accommodation reaction—cerebral syphilis is more likely. It can become almost impossible to differentiate cerebral syphilis from the prodromal or initial stage of paralysis when bilateral nonreactivity of the pupils, manifestations of intellectual fatigue or exhaustion, recurrent headaches, and hypochondriacal depression are present. In such cases, a decision as to the diagnosis is only possible following most precise observation of the course of the illness and, above all, of the influence of antisyphilitic treatments. However, it must never be forgotten that, in keeping with the anatomic demonstration of the simultaneous presence of specific and postsyphilitic brain disease, the clinical features of both conditions can also occur together at an early stage, thus making discrimination impossible.

Differential diagnosis between alcoholic and paretic dementia has long concerned psychiatrists. The very term *alcoholic pseudoparesis* is an indication of the close clinical kinship of the two illnesses. The mental devastation, lack of judgment, and dulled affect can certainly have the same qualities in both. The somatic manifestations, too, are similar to those of paresis, especially in the cases of alcoholic dementia with concomitant neuritic disease affecting peripheral nerves; paralysis of the facial and hypoglossal nerves, paretic weakness of the muscles of the extremities and trunk, tremor, impaired conductivity, and suppression of the tendon reflexes provide ample opportunity for confusion. However, if the pupillary movement in response to light stimuli is not impaired, if the speech, while tremulous, is not hesitant, and if the patient is mentally dull but does not show the lack of judgment typical for those affected by paresis with respect to the entire complex of self-images, then the diagnosis will tend toward alcoholic dementia. Nonetheless, it is mostly the course of the illness that shows us whether our diagnosis is correct. Even severe forms of alcoholic dementia are amenable to cure or recovery if the noxious influence—the abuse of spirits—can be avoided, while paresis with progressive dementia never shows remissions. The somatic features of alcoholic pseudoparesis, too (tremor, paresis, loss of tendon reflexes, and impaired sensitivity), especially when precipitated by a peripheral nerve disease, can be completely reversed. In such cases, however, we must always bear in mind that the boundaries between alcoholic and paretic dementia are fluid.

Recently, cases of psychosis have been described that have occurred following acute (toxic?) [*editor's note: author's parentheses*] polyneuritis. These cases are characterized by marked psychic agitation, incoherent and agitated succession of images with loss of orientation, and poor memory for the recent past (Korsakoff). These psychic disturbances are encountered in an analogous form in cases of paresis with an acute course, so that the two conditions can be confused if the signs of polyneuritis are overlooked or cannot be observed because of high-grade mental agitation and confusion in the patient.

The only one of the different clinical varieties of paresis that needs to be mentioned separately is taboparesis. If paretic disease accompanies classic tabes that has already been present for some years, the course of the paralytic disease is often very prolonged (lasting 8 to 10 years). The intellectual deficiency progresses very slowly; even when finer aesthetic and ethical ideas and feelings are profoundly prejudiced, the patient's memory and judgment for all other mental processes may nonetheless have suffered only an extremely slight deterioration. Patients of this type become coarse, unfeeling, and choleric and lose all sense of decency in thought and action, but they are still perfectly able to carry out coherent and complicated mental operations, particularly if they were educated, intellectually highly gifted persons before their illness; for example, they are still able to perform literary work, which demands good comprehension and memory. Even severe attacks of paralysis or intercurrent spells of agitation with acute onset, often of some weeks' duration, and occasionally a completely confused state, are not characterized by such limited intellectual defects in the first and second years during which these are not at all apparent to outsiders but only the closest members of the patient's family, eg, wife and children, notice them as manifestations of ethical impoverishment and strange personality changes. The illness is often misdiagnosed at this stage because the patient still has enough self-control and thought and speech patterns are sufficiently logical and reasonable to enable the patient to deceive the physician as to the severity and implications of these ethical defects. In such cases, it is very easy for the physician to assume that he is confronted with an instance of the emotional irritability that is so frequently associated with tabes. However, a more precise intelligence test will show that there really are deficiencies in the ethical field.

The patient can no longer properly honor his obligations in this area. He is completely unaware of his tactlessness and the ethical solecisms he commits. His judgment concerning his personal affairs, particularly his material or financial assets, is also severely impaired; he is careless and wasteful. Disturbances not belonging to the conventional clinical picture of tabes can also be found in the somatic sector: paresis of the oral branch of the facial nerve and hesitation in speech are usually seen during the course of a reasonably long observation period.

The practical importance of these cases and their differentiation from simple tabes become particularly clear when the physician is approached about protection from the patient and commitment to an institution is considered. I was recently in the position of having to assess a case of this kind, in which the patient vigorously denied the existence of any mental illness and repudiated what his relatives said as slanderous. It was not possible to commit him to an institution for quite some time, as more distant relatives and the forensic medical expert denied the presence of paretic mental illness.

To conclude my remarks, I must consider the differentiation of paresis from the states of functional exhaustion that we have recently started to include under the concept of neurasthenia. In severe cases with a long course, neurasthenia passes imperceptibly into hypochondria; the exhaustion neurosis develops into an exhaustion psychosis. If we consider the cause of both, the overstretching of the nervous work output, it is easy to understand that their precise differentiation from progressive paresis can be extremely difficult, at least in the earliest phases, whether regarded from the point of view of the origin or of the clinical picture. What criteria guarantee that in one case only a functional attrition is present, with the possibility of complete recovery, while in another case with very similar symptoms the functional overuse has already led to irreversible material damage? In the so-called prodromal stages, it is completely impossible to differentiate precisely between functional symptoms of inhibition or exhaustion and lasting symptoms of intellectual loss. To make allowance for this problem, there has often been mention of a neurasthenic preliminary stage of paresis. It is impossible to make a definite diagnosis of paresis when unmistakable somatic symptoms of deficiency (paradoxal sign and nonreactive pupils) are present, while slight asymmetry of the facial innervation, slight speech disturbances (not uncommon in neurasthenics in the presence of affective agitation or against a background of hypochondriacal compulsive ideas), giddiness, and the entire multitude of subjective symptoms of illness can only be used for the differential diagnosis with caution and with due consideration for the full range of manifestations of the illness.

If objective signs of any organic disease of the brain and spinal cord are lacking, and if we have recourse mainly to the assessment of the psychic condition in establishing a diagnosis of paresis, all sorts of mistaken diagnoses are possible in addition to confusion with neurasthenia and hypochondria. As is well known, the affective and intellectual symptoms of incipient paralysis can mimic every functional psychosis. Confusion with mania and/or melancholia is the most common mistake. In the case of hallucinatory agitation, too, however, differentiation from acute hallucinatory paranoia, but especially amentia (exhaustion psychosis), is rather uncertain. In all these pictures of paresis, the psychic deficiency symptoms, the lack of judgment, the lacking ethical sense, and the memory impairment can be concealed by an imbalance of stimulatory and inhibitory processes (excessively cheerful or mournful mood, anxious affect, motor agitation, flight of ideas, hallucinations, etc). The diagnosis is confirmed as soon as the decisive feature of the illness, ie, dementia, can be observed. In this, we can always most safely be led by exploration of the assets in terms of ethical and aesthetic feelings and ideas and the quality of the judgmental associations relating to the relationship of the patient's own personality to the processes of the outside world. If defects are found in these areas, there can hardly be any further doubt that a diagnosis of paralysis is appropriate.

As this review of the discrimination of paresis from other disease states bordering on paresis shows us, there are cliffs enough against which the diagnosis can come to grief. Differentiation of the different forms of organic brain disease is predominantly of purely scientific interest. From the point of view of the prognosis, all these different types of illness affecting the central nervous system are equivalent; that is, they all ultimately lead to disintegration of the intellectual capacities. The only exception is cerebral syphilis, which is amenable to a complete cure if therapeutic intervention is instituted sufficiently early and is sufficiently vigorous. The differential diagnosis between this condition and paresis is therefore the one that has the greatest practical significance.

Discrimination of paresis from the functional neuroses and psychoses is of practically equal importance. Among colleagues, I need say no more on the subject of how ominous mistakes in this area of differential diagnosis can be, not just for the future of our patients but also for the physical and mental well being of their families.

COMMENTARY

In recent years, Binswanger's disease has become a topic of renewed interest and controversy.[1-4] Despite comprehensive reviews, a complete translation of Binswanger's original report into English is not yet readily available.[5] The present translation attempts to retain the tone of the late 19th century scholarly language, which is now rather stilted in German as in English. The German word "paralyse" has been translated as "paresis" or sometimes as "general paresis" when it clearly refers to the condition caused by syphilis, and otherwise as "paralysis." Latin terminology has generally been translated into American usage.

Binswanger's goal was to distinguish purely vascular disease of the brain from the progressive paresis that was so prevalent in his time as to dominate neuropsychiatry. In his lecture, he discussed the characteristics of progressive paresis and contrasted them with the clinical and neuropathologic findings in the two forms of vascular brain disease that he called "chronic progressive subcortical encephalitis" (now called Binswanger's disease) and "arteriosclerotic brain degeneration."

The characteristics of chronic progressive subcortical degeneration were, clinically, onset at the threshhold of old age or in the senium; a protracted course; reduction in intellectual capacities, with early impairments of associations, complex skills, and focal deficits; and later agitation, paranoia, seizures, disturbances of consciousness, and eventually a decerebrate state. The neuropathologic characteristics were atrophy of white matter, particularly in the occipital and temporal lobes, with very little involvement of the frontal white matter and only minimal cortical atrophy. The damage was particularly to association fibers. The basal and posterior horns of the ventricles were enlarged, whereas the anterior parts of the lateral ventricles were expanded only very little. The cerebral vessels showed evidence of severe atherosclerosis.

The characteristics of arteriosclerotic brain degeneration were clinically identical to those of chronic progressive subcortical degeneration, with the important exception that isolated, focal deficits dominated the clinical picture from the beginning. The clinical deficits were intermittent and included reduction in intellectual capacities, including short-term memory, perception, acquisition, and other areas of cognition. Emotional lability occurred early, and more persistent personality changes emerged as the condition progressed. Pathologically, the condition was associated with generalized as well as cerebral atherosclerosis, with atrophy or fatty degeneration of both the small arteries and veins in both the cortex and white matter. Focal lesions were prominent, as was diffuse loss of cortical neurons.

In summary, Binswanger distinguished not only between general paresis and cerebrovascular disease but between two broad forms of cerebrovascular disease: a subcortical white-matter disease and a more general condition involving both gray and white matter. In chronic progressive subcortical encephalitis, the brain tissue changes appeared to be confined to white matter only and particularly to the areas supplied by the posterior cerebral artery. In contrast, in arteriosclerotic brain degeneration, changes were evident in both gray *and* white matter and were not confined to an area supplied by a specific cerebral artery.

In 1895, Binswanger lectured further about the "Delineation of General Paresis,"[6] repeating the views he had presented in 1893. He emphasized the existence of two different vascular diseases of the brain, one affecting primarily white matter. In the discussion of this lecture,[7] Alois Alzheimer emphasized that Binswanger was the first to attempt to separate two different arteriosclerotic brain diseases from general paresis. Alzheimer himself also reported on "arteriosclerotic atrophy of the brain."[8] According to Alzheimer, the onset of disease was between ages 45 and

55 years, with men affected more often than women. Generalized atherosclerosis was typically present. Prodromes included headache, vertigo, rapid fatigue, and emotional lability. Then memory loss developed, followed by global cognitive impairments and instability of affect. Pathologically, there was generalized atherosclerosis. Relatively little atrophy of cereberal cortical or other brain structures occurred. Within the cortex, there were foci of degeneration, with small aneurysms and multiple small areas of hemorrhage and gliosis surrounding degenerating vessels. Alzheimer suggested that because of the distinct clinical symptoms, course, and neuropathologic findings, "one may have reasons enough to distinguish arteriosclerotic atrophy of the brain as a disease on its own distinct from other brain diseases."

In 1910, in his widely used textbook, Emil Kraepelin described Alzheimer's "senile brain devastation" as a consequence of senile arteriosclerosis, particularly in small vessels entering the cortex from the brain surface.[9] He proposed that these vessels occlude gradually, leading to a simple atrophy of nerve tissue.[10]

Within the last 5 years, Binswanger's disease has become a subject of renewed interest and controversy, particularly in reference to the white-matter changes evident on computed tomographic scans and magnetic resonance images.[1-4,11-19] When Binswanger wrote the article that is translated herein, the new stains recently developed by Nissl and Weigert were on the cutting edge of neuroscience research, and computerized brain imaging was unimaginable. It is therefore gratifying that Binswanger's clinical insights may still be relevant nearly 100 years later. He recognized that the clinical signs and symptoms of vascular damage to white matter, like the clinical manifestations of vascular damage to the gray matter that provide the cells of origin of the fibers in white matter, depend in large part on the location and extent of tissue damaged. He recognized that the amount of brain damage necessary to push a patient across the threshhold of clinical disability depended in part on how much brain function the patient had premorbidly and in part on how much was demanded of the patient in the way of performance. Those insights may be relevant to the clinical variability that has been associated with evidence of white-matter damage in imaging studies, including the evidence of marked radiologic abnormalities in people with no clinically important disabilities.

Binswanger's observation that vascular damage to white matter can occur with relatively little damage to gray matter is in accord with subsequent experimental studies in animals. Thus, controlled hypoxemia (arterial Po_2, 28 to 30 mm Hg) increased 2-deoxyglucose utilization in white matter in columns associated with penetrating arteries, with little effect on gray matter.[20] This relative vulnerability of white matter was attributed to a less extensive blood supply. Binswanger's observation of relatively selective damage to the white matter supplied by the posterior cerebral artery may relate to subsequent observations of anatomic differences among the cerebral arteries.[21] Among the important differences between Binswanger's time and the present is the age at onset of the senium, which Binswanger put at 60 years but which is now more often put by geriatricians in the middle or late 70s.[22]

It is hoped that the availability of this classic article to those who easily read English but not German will facilitate the continued contribution of Binswanger's original insights into the complex problems of dementing diseases, including the condition that has given him eponymic medical immortality.

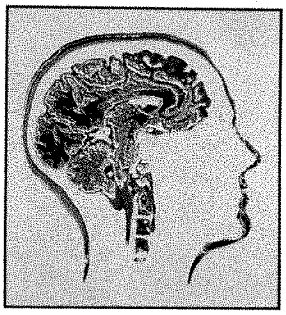
THROUGH A CALCIUM-MODULATING MECHANISM OF ACTION



CEREBROSELECTIVE

NIMOTOP®

nimodipine/Miles

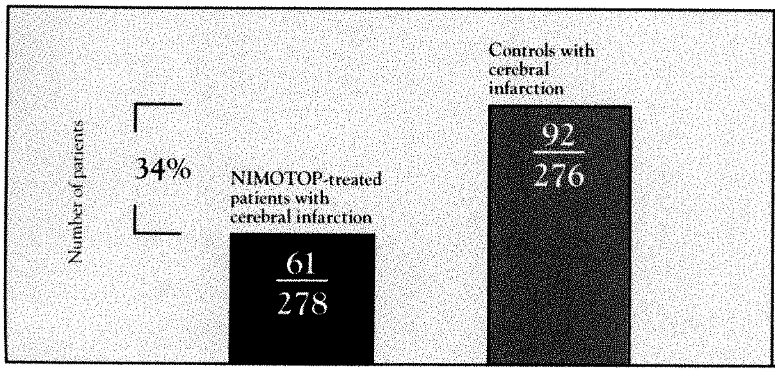
CAPSULES 30 mg

REDUCES INCIDENCE OF CEREBRAL INFARCTION IN PATIENTS FOLLOWING SUBARACHNOID HEMORRHAGE

In the largest study to date, NIMOTOP demonstrated a significant reduction in incidence of cerebral infarction[1]

- Twenty-two percent (61/278) of NIMOTOP-treated patients experienced cerebral infarction vs. 33% (92/276) of controls
- NIMOTOP reduced the incidence of cerebral infarction by 34%

Thirty-four percent reduction in incidence of cerebral infarction with NIMOTOP-treated patients vs. controls (n=554; p=0.003)[1]*



*90% of patients in this study were Hunt and Hess Grades I-III.

Dose: 60 mg (two 30 mg liquid-filled capsules) every 4 hours for 21 days commencing within 96 hours of SAH.

Adapted from Pickard, et al.[1]

NIMOTOP modulates calcium influx to promote cerebral perfusion, and may directly protect neurons[2-5]

"[In animals] The beneficial cytoprotective effect of nimodipine, probably related to normalization of calcium homeostasis and blood-brain barrier permeability after ischemia, may reflect both vascular and cellular sites of action."[6]
Lazarewicz JW, et al. *Stroke* 1989.

"[In humans] The data thus suggest that nimodipine neither prevents nor reverses cerebral vasospasm. Calcium channel blockers such as nimodipine may have an effect on cerebral arterioles that are below the limits of resolution of angiography. . . . "[1]
Pickard JD, et al. *Br Med J* 1989.

Please see references and Brief Summary of full prescribing information on next page.

MILES

CEREBROSELECTIVE

NIMOTOP®

nimodipine/Miles

CAPSULES 30 mg

NIMOTOP REDUCES THE INCIDENCE OF CEREBRAL INFARCTION FOLLOWING SUBARACHNOID HEMORRHAGE

BRIEF SUMMARY
NIMOTOP® (nimodipine/Miles) CAPSULES
For Oral Use

INDICATIONS AND USAGE

Nimotop® (nimodipine) is indicated for the improvement of neurological deficits due to spasm following subarachnoid hemorrhage from ruptured congenital intracranial aneurysms in patients who are in good neurological condition post-ictus (e.g. Hunt and Hess Grades I-III). Oral Nimotop® therapy should begin within 96 hours of the subarachnoid hemorrhage and continue for 21 days.

CONTRAINDICATIONS

None known.

PRECAUTIONS

General: Blood Pressure: Nimodipine has the hemodynamic effects expected of a calcium channel blocker, although they are generally not marked. In patients with subarachnoid hemorrhage given Nimotop® in clinical studies, about 5% were reported to have had lowering of the blood pressure and about 1% left the study because of this (not all could be attributed to nimodipine). Nevertheless, blood pressure should be carefully monitored during treatment with Nimotop® based on its known pharmacology and the known effects of calcium channel blockers.

Hepatic Disease: The metabolism of Nimotop® is decreased in patients with impaired hepatic function. Such patients should have their blood pressure and pulse rate monitored closely and should be given a lower dose (see Dosage and Administration).

Laboratory Test Interactions: None known.

Drug Interaction: It is possible that the cardiovascular action of other calcium channel blockers could be enhanced by the addition of Nimotop®.

In Europe, Nimotop® was observed to occasionally intensify the effect of antihypertensive compounds taken concomitantly by patients suffering from hypertension: this phenomenon was not observed in North American clinical trials.

Carcinogenesis, Mutagenesis, Impairment of Fertility: In a two-year study, higher incidences of adenocarcinoma of the uterus and Leydig-cell adenoma of the testes were observed in rats given a diet containing 1800 ppm nimodipine (equivalent to 91 to 121 mg/kg/day nimodipine) than in placebo controls. The differences were not statistically significant; however, the higher rates were well within historical control range for these tumors in the Wistar strain. Nimodipine was found not to be carcinogenic in a 91-week mouse study but the high dose of 1800 ppm nimodipine-in-feed (546 to 774 mg/kg/day) shortened the life expectancy of the animals. Mutagenic studies, including the Ames, micronucleus and dominant lethal tests were negative.

Nimodipine did not impair the fertility and general reproductive performance of male and female Wistar rats following oral doses of up to 30 mg/kg/day when administered daily for more than 10 weeks in the males and 3 weeks in the females prior to mating and continued to day 7 of pregnancy. This dose in a rat is about 4 times the equivalent clinical dose of 60 mg q4h in a 50 kg patient.

Pregnancy: Pregnancy Category C. Nimodipine has been shown to have a teratogenic effect in Himalayan rabbits. Incidences of malformations and stunted fetuses were increased at oral (by gavage) doses of 1 and 10 mg/kg/day administered from day 6 through day 18 of pregnancy but not at 3.0 mg/kg/day in one of two identical rabbit studies. In the second study an increased incidence of stunted fetuses was seen at 1.0 mg/kg/day but not at higher doses. Nimodipine was embryotoxic, causing resorption and stunted growth of fetuses, in Long Evans rats at 100 mg/kg/day administered by gavage from day 6 through day 15 of pregnancy. In two other rat studies, doses of 30 mg/kg/day nimodipine administered by gavage from day 16 of gestation and continued until sacrifice (day 20 of pregnancy or day 21 post partum) were associated with higher incidences of skeletal variation, stunted fetuses and stillbirths but no malformations. There are no adequate and well controlled studies in pregnant women to directly assess the effect on human fetuses. Nimodipine should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: Nimodipine and/or its metabolites have been shown to appear in rat milk at concentrations much higher than in maternal plasma. It is not known whether the drug is excreted in human milk. Because many drugs are excreted in human milk, nursing mothers are advised not to breast feed their babies when taking the drug.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

Adverse experiences were reported by 92 of 823 patients with subarachnoid hemorrhage (11.2%) who were given nimodipine. The most frequently reported adverse experience was decreased blood pressure in 4.4% of these patients. Twenty-nine of 479 (6.1%) placebo treated patients also reported adverse experiences. The events reported with a frequency greater than 1% are displayed below by dose.

DOSE q4h
Number of Patients (%)

	Nimodipine					Placebo
Sign/Symptom	**0.35 mg/kg (n = 82)**	**30 mg (n = 71)**	**60 mg (n = 494)**	**90 mg (n = 172)**	**120 mg (n = 4)**	**(n = 479)**
Decreased Blood Pressure	1 (1.2)	0	19 (3.8)	14 (8.1)	2 (50.0)	6 (1.2)
Abnormal Liver Function Test	1 (1.2)	0	2 (0.4)	1 (0.6)	0	7 (1.5)
Edema	0	0	2 (0.4)	2 (1.2)	0	3 (0.6)
Diarrhea	0	3 (4.2)	0	3 (1.7)	0	3 (0.6)
Rash	2 (2.4)	0	3 (0.6)	2 (1.2)	0	3 (0.6)
Headache	0	1 (1.4)	6 (1.2)	0	0	1 (0.2)
Gastrointestinal Symptoms	2 (2.4)	0	0	2 (1.2)	0	0
Nausea	1 (1.2)	1 (1.4)	6 (1.2)	1 (0.6)	0	0
Dyspnea	1 (1.2)	0	0	0	0	0
EKG Abnormalities	0	1 (1.4)	0	1 (0.6)	0	0
Tachycardia	0	1 (1.4)	0	0	0	0
Bradycardia	0	0	5 (1.0)	1 (0.6)	0	0
Muscle Pain/Cramp	0	1 (1.4)	1 (0.2)	1 (0.6)	0	0
Acne	0	1 (1.4)	0	0	0	0
Depression	0	1 (1.4)	0	0	0	0

There were no other adverse experiences reported by the patients who were given 0.35 mg/kg q4h, 30 mg q4h or 120 mg q4h. Adverse experiences with an incidence rate of less than 1% in the 60 mg q4h dose group were: hepatitis; itching; gastrointestinal hemorrhage; thrombocytopenia; anemia; palpitations; vomiting; flushing; diaphoresis; wheezing; phenytoin toxicity; lightheadedness; dizziness; rebound vasospasm; jaundice; hypertension; hematoma.

Adverse experiences with an incidence rate less than 1% in the 90 mg q4h dose group were: itching; gastrointestinal hemorrhage; thrombocytopenia; neurological deterioration; vomiting; diaphoresis; congestive heart failure; hyponatremia; decreasing platelet count; disseminated intravascular coagulation; deep vein thrombosis.

As can be seen from the table, side effects that appear related to nimodipine use based on increased incidence with higher dose or a higher rate compared to placebo control, included decreased blood pressure, edema and headaches which are known pharmacologic actions of calcium channel blockers. It must be noted, however, that SAH is frequently accompanied by alterations in consciousness which lead to an under reporting of adverse experiences. Patients who received nimodipine in clinical trials for other indications reported flushing (2.1%), headache (4.1%) and fluid retention (0.3%), typical responses to calcium channel blockers. As a calcium channel blocker, nimodipine may have the potential to exacerbate heart failure in susceptible patients or to interfere with A-V conduction, but these events were not observed.

No clinically significant effects on hematologic factors, renal or hepatic function or carbohydrate metabolism have been causally associated with oral nimodipine. Isolated cases of non-fasting elevated serum glucose levels (0.8%), elevated LDH levels (0.4%), decreased platelet counts (0.3%), elevated alkaline phosphatase levels (0.2%) and elevated SGPT levels (0.2%) have been reported rarely.

OVERDOSAGE

There have been no reports of overdosage from the oral administration of Nimotop®. Symptoms of overdosage would be expected to be related to cardiovascular effects such as excessive peripheral vasodilation with marked systemic hypotension. Clinically significant hypotension due to Nimotop® overdosage may require active cardiovascular support. Norepinephrine or dopamine may be helpful in restoring blood pressure. Since Nimotop® is highly protein-bound, dialysis is not likely to be of benefit.

DOSAGE AND ADMINISTRATION

Nimotop® is given orally in the form of ivory colored, soft gelatin 30 mg capsules for subarachnoid hemorrhage.

The oral dose is 60 mg (two 30 mg capsules) every 4 hours for 21 consecutive days. Oral Nimotop® therapy should commence within 96 hours of the subarachnoid hemorrhage.

If the capsule cannot be swallowed, e.g., at the time of surgery, or if the patient is unconscious, a hole should be made in both ends of the capsule with an 18 gauge needle, and the contents of the capsule extracted into a syringe. The contents should then be emptied into the patient's *in situ* naso-gastric tube and washed down the tube with 30 mL of normal saline (0.9%).

Patients with hepatic failure have substantially reduced clearance and approximately doubled C_{max}. Dosage should be reduced to 30 mg every 4 hours, with close monitoring of blood pressure and heart rate.

HEADACHE DESCRIBED

"Headache"– a personal interpretation of headache pain by John Crowley, a headache patient.

HEADACHE RELIEVED

Effectively treats the pain of muscle contraction headache as well as the anxiety and tension that magnify it

FIORINAL® WITH CODEINE CAPSULES Ⓒ III

(Each capsule contains: codeine phosphate 30 mg [Warning: May be habit-forming]; butalbital 50 mg [Warning: May be habit-forming]; caffeine 40 mg; and aspirin 325 mg)

Potent relief of tension headache pain

Please see brief summary on following page.

SANDOZ

SANDOZ PHARMACEUTICALS CORPORATION
EAST HANOVER, NEW JERSEY 07936

5/91 Printed in U.S.A. FWC-1290-01

©1991 Sandoz Pharmaceuticals Corporation

BRIEF SUMMARY: Please see package insert for full prescribing information.

FIORINAL® WITH CODEINE (III CAPSULES

(Codeine phosphate USP, 30 mg [warning: may be habit forming]; butalbital USP, 50 mg [warning: may be habit forming]; caffeine USP, 40 mg; aspirin USP, 325 mg)

CAUTION: Federal law prohibits dispensing without prescription.

CONTRAINDICATIONS: Fiorinal® with Codeine is contraindicated under the following conditions:

1. Hypersensitivity or intolerance to aspirin, caffeine, butalbital or codeine.
2. Patients with a hemorrhagic diathesis (e.g., hemophilia, hypoprothrombinemia, von Willebrand's disease, the thrombocytopenias, thrombasthenia and other ill-defined hereditary platelet dysfunctions, severe vitamin K deficiency and severe liver damage.)
3. Patients with the syndrome of nasal polyps, angioedema and bronchospastic reactivity to aspirin or other nonsteroidal anti-inflammatory drugs. Anaphylactoid reactions have occurred in such patients.
4. Peptic ulcer or other serious gastrointestinal lesions.
5. Patients with porphyria.

WARNINGS: Therapeutic doses of aspirin can cause anaphylactic shock and other severe allergic reactions. It should be ascertained if the patient is allergic to aspirin, although a specific history of allergy may be lacking.

Significant bleeding can result from aspirin therapy in patients with peptic ulcer or other gastrointestinal lesions, and in patients with bleeding disorders.

Aspirin administered pre-operatively may prolong the bleeding time.

In the presence of head injury or other intracranial lesions, the respiratory depressant effects of codeine and other narcotics may be markedly enhanced, as well as their capacity for elevating cerebrospinal fluid pressure. Narcotics also produce other CNS depressant effects, such as drowsiness, that may further obscure the clinical course of patients with head injuries.

Codeine or other narcotics may obscure signs on which to judge the diagnosis or clinical course of patients with acute abdominal conditions.

Butalbital and codeine are both habit-forming and potentially abusable. Consequently, the extended use of Fiorinal® with Codeine is not recommended.

Results from epidemiologic studies indicate an association between aspirin and Reye Syndrome. Caution should be used in administering this product to children, including teenagers, with chicken pox or flu.

PRECAUTIONS: General: Fiorinal® with Codeine should be prescribed with caution for certain special-risk patients such as the elderly or debilitated, and those with severe impairment of renal or hepatic function, coagulation disorders, or head injuries.

Aspirin should be used with caution in patients on anticoagulant therapy and in patients with underlying hemostatic defects.

Precautions should be taken when administering salicylates to persons with known allergies. Hypersensitivity to aspirin is particularly likely in patients with nasal polyps, and relatively common in those with asthma.

Information for Patients: Patients should be informed that Fiorinal® with Codeine contains aspirin and should not be taken by patients with an aspirin allergy.

Fiorinal® with Codeine may impair the mental and/or physical abilities required for performance of potentially hazardous tasks such as driving a car or operating machinery. Such tasks should be avoided while taking Fiorinal® with Codeine.

Alcohol and other CNS depressants may produce an additive CNS depression when taken with Fiorinal® with Codeine, and should be avoided.

Codeine and butalbital may be habit-forming. Patients should take the drug only for as long as it is prescribed, in the amounts prescribed, and no more frequently than prescribed.

Laboratory Tests: In patients with severe hepatic or renal disease, effects of therapy should be monitored with serial liver and/or renal function tests.

Drug Interactions: The CNS effects of butalbital may be enhanced by monoamine oxidase (MAO) inhibitors.

In patients receiving concomitant corticosteroids and chronic use of aspirin, withdrawal of corticosteroids may result in salicylism because corticosteroids enhance renal clearance of salicylates and their withdrawal is followed by return to normal rates of renal clearance.

Fiorinal® with Codeine may enhance the effects of:

1. Oral anticoagulants, causing bleeding by inhibiting prothrombin formation in the liver and displacing anticoagulants from plasma protein binding sites.
2. Oral antidiabetic agents and insulin, causing hypoglycemia by contributing an additive effect, if dosage of Fiorinal® with Codeine exceeds maximum recommended daily dosage.
3. 6-mercaptopurine and methotrexate, causing bone marrow toxicity and blood dyscrasias by displacing these drugs from secondary binding sites, and, in the case of methotrexate, also reducing its excretion.
4. Non-steroidal anti-inflammatory agents, increasing the risk of peptic ulceration and bleeding by contributing additive effects.
5. Other narcotic analgesics, alcohol, general anesthetics, tranquilizers such as chlordiazepoxide, sedative-hypnotics, or other CNS depressants, causing increased CNS depression.

Fiorinal® with Codeine may diminish the effects of: Uricosuric agents such as probenecid and sulfinpyrazone, reducing their effectiveness in the treatment of gout. Aspirin competes with these agents for protein binding sites.

Drug/Laboratory Test Interactions

Aspirin: Aspirin may interfere with the following laboratory determinations in blood: serum amylase, fasting blood glucose, cholesterol, protein, serum glutamic-oxalacetic transaminase (SGOT), uric acid, prothrombin time and bleeding time. Aspirin may interfere with the following laboratory determinations in urine: glucose, 5-hydroxyindoleacetic acid, Gerhardt ketone, vanillylmandelic acid (VMA), uric acid, diacetic acid, and spectrophotometric detection of barbiturates.

Codeine: Codeine may increase serum amylase levels.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Adequate long-term studies have been conducted in mice and rats with aspirin, alone or in combination with other drugs, in which no evidence of carcinogenesis was seen. No adequate studies have been conducted in animals to determine whether aspirin has a potential for mutagenesis or impairment of fertility. No adequate studies have been conducted in animals to determine whether butalbital has a potential for carcinogenesis, mutagenesis, or impairment of fertility.

Usage in Pregnancy

Teratogenic Effects: Pregnancy Category C — Animal reproduction studies have not been conducted with Fiorinal® with Codeine. It is also not known whether Fiorinal® with Codeine can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Fiorinal® with Codeine should be given to a pregnant woman only when clearly needed.

Nonteratogenic Effects: Although Fiorinal® with Codeine was not implicated in the birth defect, a female infant was born with lissencephaly, pachygyria and heterotopic gray matter. The infant was born 8 weeks prematurely to a woman who had taken an average of 90 Fiorinal® with Codeine capsules each month from the first few days of pregnancy. The child's development was mildly delayed and from one year of age she had partial simple motor seizures.

Withdrawal seizures were reported in a two-day-old male infant whose mother had taken a butalbital-containing drug during the last 2 months of pregnancy. Butalbital was found in the infant's serum. The infant was given phenobarbital 5mg/kg, which was tapered without further seizure or other withdrawal symptoms.

Studies of aspirin use in pregnant women have not shown that aspirin increases the risk of abnormalities when administered during the first trimester of pregnancy. In controlled studies involving 41,337 pregnant women and their offspring, there was no evidence that aspirin taken during pregnancy caused stillbirth, neonatal death or reduced birth weight. In controlled studies of 50,282 pregnant women and their offspring, aspirin administration in moderate and heavy doses during the first four lunar months of pregnancy showed no teratogenic effect.

Reproduction studies have been performed in rabbits and rats at doses up to 150 times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to codeine.

Therapeutic doses of aspirin in pregnant women close to term may cause bleeding in mother, fetus, or neonate. During the last 6 months of pregnancy, regular use of aspirin in high doses may prolong pregnancy and delivery.

Labor and Delivery: Ingestion of aspirin prior to delivery may prolong delivery or lead to bleeding in the mother or neonate. Use of codeine during labor may lead to respiratory depression in the neonate.

Nursing Mothers: Aspirin, caffeine, barbiturates and codeine are excreted in breast milk in small amounts, but the significance of their effects on nursing infants is not known. Because of potential for serious adverse reactions in nursing infants from Fiorinal® with Codeine, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use: Safety and effectiveness in children below the age of 12 have not been established.

ADVERSE REACTIONS: Commonly Observed: The most commonly reported adverse events associated with the use of Fiorinal® with Codeine and not reported at an equivalent incidence by placebo-treated patients were nausea and/or abdominal pain, drowsiness, and dizziness.

Associated with Treatment Discontinuation: Of the 382 patients treated with Fiorinal® with Codeine in controlled clinical trials, three (0.8%) discontinued treatment with Fiorinal® with Codeine because of adverse events. One patient each discontinued treatment for the following reasons: gastrointestinal upset; lightheadedness and heavy eyelids; and drowsiness and generalized tingling.

Incidence in Controlled Clinical Trials: The following table summarizes the incidence rates of the adverse events reported by at least 1% of the Fiorinal® with Codeine treated patients in controlled clinical trials comparing Fiorinal® with Codeine to placebo, and provides a comparison to the incidence rates reported by the placebo-treated patients.

The prescriber should be aware that these figures cannot be used to predict the incidence of side effects in the course of usual medical practice where patient characteristics and other factors differ from those that prevailed in the clinical trials. Similarly, the cited frequencies cannot be compared with figures obtained from other clinical investigations involving different treatments, uses, and investigators.

Adverse Events Reported by at Least 1% of Fiorinal® with Codeine Treated Patients During Placebo Controlled Clinical Trials

	Incidence Rate of Adverse Events	
Body System/ Adverse Event	Fiorinal®/Codeine (N = 382)	Placebo (N = 377)
Central Nervous		
Drowsiness	2.4%	0.5%
Dizziness/Lightheacedness	2.6%	0.5%
Intoxicated Feeling	1.0%	0%
Gastrointestinal		
Nausea/Abdominal Pain	3.7%	0.8%

Other Adverse Events Reported During Controlled Clinical Trials: The listing that follows represents the proportion of the 382 patients exposed to Fiorinal® with Codeine while participating in the controlled clinical trials who reported, on at least one occasion, an adverse event of the type cited. All reported adverse events, except those already presented in the previous table, are included. It is important to emphasize that, although the adverse events reported did occur while the patient was receiving Fiorinal® with Codeine, the adverse events were not necessarily caused by Fiorinal® with Codeine.

Adverse events are classified by body system and frequency. "Frequent" is defined as an adverse event which occurred in at least 1/100 (1%) of the patients; all adverse events listed in the previous table are frequent. "Infrequent" is defined as an adverse event that occurred in less than 1/100 patients but at least 1/1000 patients. All adverse events tabulated below are classified as infrequent.

Central Nervous: headache, shaky feeling, tingling, agitation, fainting, fatigue, heavy eyelids, high energy, hot spells, numbness, and sluggishness.

Autonomic Nervous: dry mouth and hyperhidrosis.

Gastrointestinal: vomiting, difficulty swallowing, and heartburn.

Cardiovascular: tachycardia.

Musculoskeletal: leg pain and muscle fatigue.

Genitourinary: diuresis.

Miscellaneous: pruritus, fever, earache, nasal congestion, and tinnitus.

Voluntary reports of adverse drug events, temporally associated with Fiorinal® with Codeine, that have been received since market introduction and that were not reported in clinical trials by the patients treated with Fiorinal® with Codeine, are listed below. Many or most of these events may have no causal relationship with the drug and are listed according to body system.

Central Nervous: Abuse, addiction, anxiety, depression, disorientation, hallucination, hyperactivity, insomnia, libido decrease, nervousness, neuropathy, psychosis, sedation, sexual activity increase, slurred speech, twitching, unconsciousness, vertigo.

Autonomic Nervous: epistaxis, flushing, miosis, salivation.

Gastrointestinal: anorexia, appetite increased, constipation, diarrhea, esophagitis, gastroenteritis, gastrointestinal spasm, hiccup, mouth burning, pyloric ulcer.

Cardiovascular: chest pain, hypotensive reaction, palpitations, syncope.

Skin: erythema, erythema multiforme, exfoliative dermatitis, hives, rash, toxic epidermal necrolysis.

Urinary: kidney impairment, urinary difficulty.

Miscellaneous: allergic reaction, anaphylactic shock, cholangiocarcinoma, drug interaction with erythromycin (stomach upset), edema.

The following adverse drug events may be borne in mind as potential effects of the components of Fiorinal® with Codeine. Potential effects of high dosage are listed in the *OVERDOSAGE* section of this insert.

Aspirin: occult blood loss, hemolytic anemia, iron deficiency anemia, gastric distress, heartburn, nausea, peptic ulcer, prolonged bleeding time, acute airway obstruction, renal toxicity when taken in high doses for prolonged periods, impaired urate excretion, hepatitis.

Caffeine: cardiac stimulation, irritability, tremor, dependence, nephrotoxicity, hyperglycemia.

Codeine: nausea, vomiting, drowsiness, lightheadedness, constipation, pruritus.

DRUG ABUSE AND DEPENDENCE: Fiorinal® with Codeine is controlled by the Drug Enforcement Administration and is classified under Schedule III.

Codeine: Codeine can produce drug dependence of the morphine type and, therefore, has the potential for being abused. Psychological dependence, physical dependence, and tolerance may develop upon repeated administration and it should be prescribed and administered with the same degree of caution appropriate to the use of other oral narcotic medications.

Butalbital: *Barbiturates may be habit forming:* Tolerance, psychological dependence, and physical dependence may occur especially following prolonged use of high doses of barbiturates. The average daily dose for the barbiturate addict is usually about 1,500 mg. As tolerance to barbiturates develops, the amount needed to maintain the same level of intoxication increases; tolerance to a fatal dosage, however, does not increase more than two-fold. As this occurs, the margin between an intoxication dosage and fatal dosage becomes smaller. The lethal dose of a barbiturate is far less if alcohol is also ingested. Major withdrawal symptoms (convulsions and delirium) may occur within 16 hours and last up to 5 days after abrupt cessation of these drugs. Intensity of withdrawal symptoms gradually declines over a period of approximately 15 days. Treatment of barbiturate dependence consists of cautious and gradual withdrawal of the drug. Barbiturate-dependent patients can be withdrawn by using a number of different withdrawal regimens. One method involves initiating treatment at the patient's regular dosage level and gradually decreasing the daily dosage as tolerated by the patient.

OVERDOSAGE: The toxic effects of acute overdosage of Fiorinal® with Codeine capsules are attributable mainly to the barbiturate and codeine components, and, to a lesser extent, aspirin. Because toxic effects of caffeine occur in very high dosages only, the possibility of significant caffeine toxicity from Fiorinal® with Codeine overdosage is unlikely.

Signs and Symptoms: Symptoms attributable to *acute barbiturate poisoning* include drowsiness, confusion, and coma; respiratory depression; hypotension; shock. Symptoms attributable to *acute aspirin poisoning* include hyperpnea; acid-base disturbances with development of metabolic acidosis; vomiting and abdominal pain; tinnitus, hyperthermia; hypoprothrombinemia; restlessness; delirium; convulsions. *Acute caffeine poisoning* may cause insomnia, restlessness, tremor, and delirium; tachycardia and extrasystoles. Symptoms of *acute codeine poisoning* include the triad of: pinpoint pupils, marked depression of respiration, and loss of consciousness. Convulsions may occur.

Treatment: The following paragraphs describe one approach to the treatment of overdose with Fiorinal® with Codeine. However, because strategies for the management of an overdose continually evolve, consultation with a regional poison control center is strongly encouraged.

Treatment consists primarily of management of barbiturate intoxication, reversal of the effects of codeine, and the correction of the acid-base imbalance due to salicylism. Vomiting should be induced mechanically or with emetics in the conscious patient. Gastric lavage may be used if the pharyngeal and laryngeal reflexes are present and if less than 4 hours have elapsed since ingestion. A cuffed endotracheal tube should be inserted before gastric lavage of the unconscious patient and when necessary to provide assisted respiration. Diuresis, alkalinization of the urine, and correction of electrolyte disturbances should be accomplished through administration of intravenous fluids such as 1% sodium bicarbonate and 5% dextrose in water.

Meticulous attention should be given to maintaining adequate pulmonary ventilation. Correction of hypotension may require the administration of levarterenol bitartrate or phenylephrine hydrochloride by intravenous infusion. In severe cases of intoxication, peritoneal dialysis, hemodialysis, or exchange transfusion may be lifesaving. Hypoprothrombinemia should be treated with vitamin K, intravenously.

Methemoglobinemia over 30% should be treated with methylene blue by slow intravenous administration.

Naloxone, a narcotic antagonist, can reverse respiratory depression and coma associated with opioid overdose. Typically, a dose of 0.4 mg to 2 mg is given parenterally and may be repeated if an adequate response is not achieved. Since the duration of action of codeine may exceed that of the antagonist, the patient should be kept under continued surveillance and repeated doses of the antagonist should be administered as needed to maintain adequate respiration. A narcotic antagonist should not be administered in the absence of clinically significant respiratory or cardiovascular depression.

Toxic and Lethal Doses:

Butalbital: toxic dose 1.0 g (adult); lethal dose 2.0-5.0 g
Aspirin: toxic blood level greater than 30 mg/100 mL; lethal dose 10-30 g (adult)
Caffeine: toxic dose greater than 1.0 g; lethal dose unknown
Codeine: lethal dose 0.5-1.0 g (adult)

SANDOZ PHARMACEUTICALS
Corporation, E. Hanover, NJ 07936 (201) 503-7500

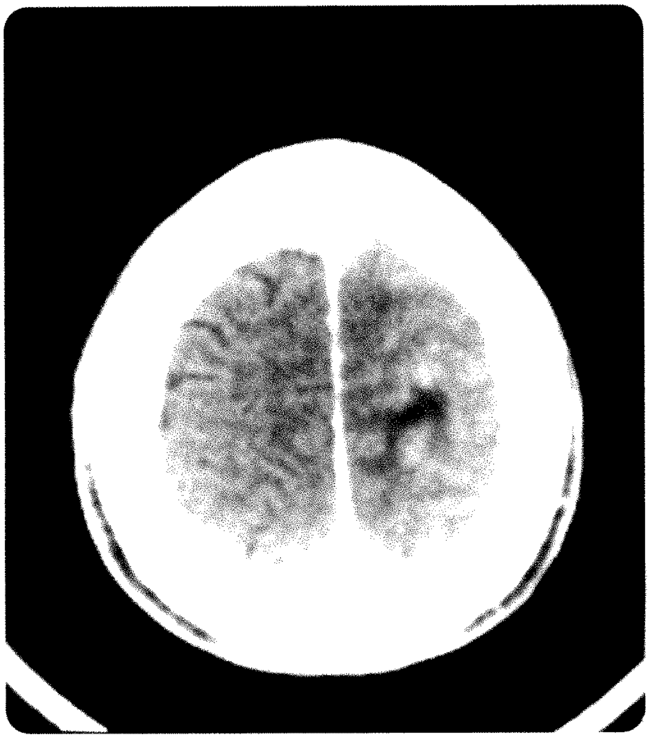
[NOVEMBER 1, 1990 FWC-Z26]

THE DECISION IS YOURS.

COMPARE.

THE CASE: A 40-year-old man presented with a 2-month history of involuntary muscle contractions of the right arm and mild weakness of the left leg.

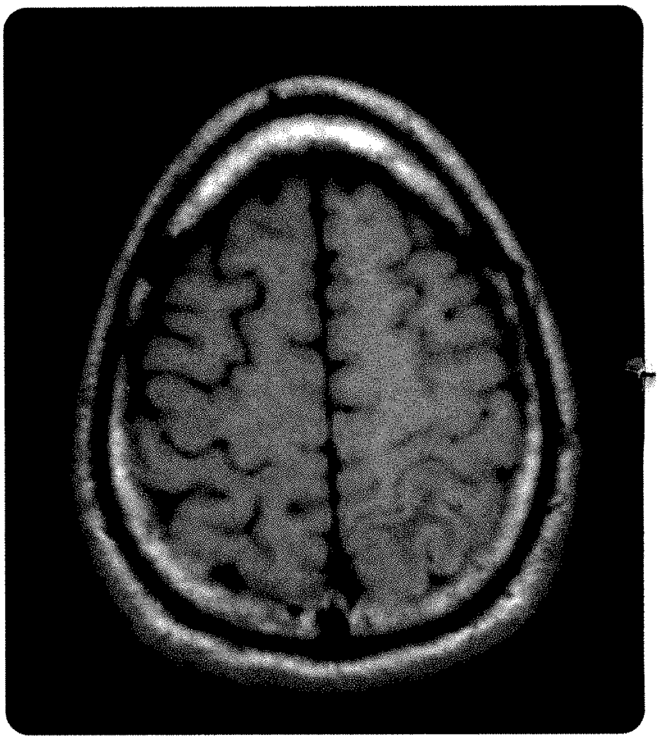
First there was CT.



Contrast CT scan shows an area of low attenuation in the left parietal lobe. A questionable focus of contrast is seen, but this may represent cerebral cortex.

Images courtesy of Michael R. Ross, MD, Stanford University Medical Center, Stanford, California

Then MRI.

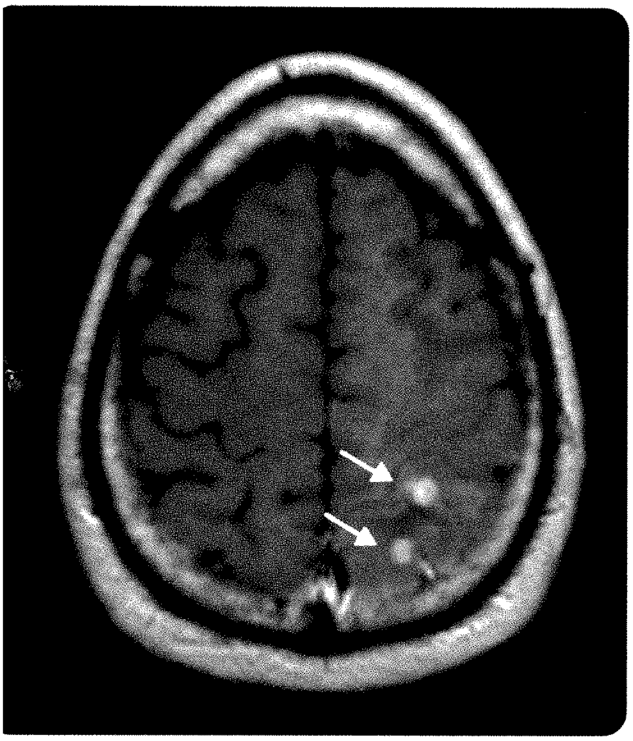


T1-weighted (TR 800/TE 20) unenhanced MR image, obtained with a 1.5-T imager, shows subcortical hypointensity in the left posterior parietal lobe. The surrounding sulci appear to be compressed, but a mass is not clearly appreciated.

© 1991, Berlex Laboratories, Inc. All rights reserved.

AND CONTRAST.

Now, *Magnevist*®-enhanced MRI lets you see even more.

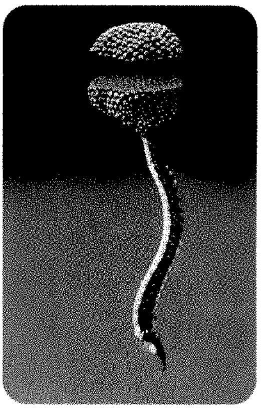


1-weighted (TR 800/TE 20) image enhanced with MAGNEVIST® injection reveals two discrete nodules arrows). This nodular enhancement is highly suggestive of a primary brain tumor, which was confirmed upon biopsy to be an astrocytoma.

Magnevist®
(gadopentetate dimeglumine 469.01 mg/mL)
INJECTION

NOTHING LOCATES LESIONS BETTER

Please see brief summary of prescribing information for MAGNEVIST® injection on last page of this advertisement.



Well tolerated[1] In clinical trials, the most common adverse reactions reported were headache (8.7%) and injection-site coldness/localized coldness (4.8%). The majority of headaches were transient and of mild to moderate severity. In clinical trials, 15% to 30% of patients experienced an asymptomatic transient rise in serum iron; hypotension and anaphylactoid reactions have occurred in less than 1% of the patients. The safety of MAGNEVIST® injection in patients with hemolytic disorders has not been studied.

REFERENCE: 1. Data on file, Berlex Laboratories, Inc.

BRIEF SUMMARY

INDICATIONS AND USAGE

MAGNEVIST® Injection is indicated for use with magnetic resonance imaging (MRI) in adults and children (2 years of age and older) to provide contrast enhancement in those intracranial lesions with abnormal vascularity or those thought to cause an abnormality in the blood-brain barrier. MAGNEVIST® Injection has been shown to facilitate visualization of intracranial lesions including but not limited to tumors.

MAGNEVIST® Injection is also indicated for use with MRI in adults and children (2 years of age and older) to provide contrast enhancement and facilitate visualization of lesions in the spine and associated tissues. There is, however, only limited clinical experience in children for this indication.

CONTRAINDICATIONS

None known.

WARNINGS

The accepted safety considerations and procedures that are required for magnetic resonance imaging are applicable when MAGNEVIST® Injection is used for contrast enhancement. In addition, deoxygenated sickle erythrocytes have been shown in *in vitro* studies to align perpendicular to a magnetic field which may result in vaso-occlusive complications *in vivo*. The enhancement of magnetic moment by gadopentetate dimeglumine may possibly potentiate sickle erythrocyte alignment. MAGNEVIST® Injection in patients with sickle cell anemia and other hemoglobinopathies has not been studied.

Patients with other hemolytic anemias have not been adequately evaluated following administration of MAGNEVIST® Injection to exclude the possibility of increased hemolysis.

Hypotension may occur in some patients after injection of MAGNEVIST® Injection. In clinical trials two cases were reported and in addition, there was one case of a vasovagal reaction and two cases of pallor with dizziness, sweating and nausea in one and substernal pain and flushing in the other. These were reported within 25 to 85 minutes after injection except for the vasovagal reaction which was described as mild by the patient and occurred after 6-1/2 hours. In a study in normal volunteers one subject experienced syncope after arising from a sitting position two hours after administration of the drug. Although the relationship of gadopentetate dimeglumine to these events is uncertain, patients should be observed for several hours after drug administration.

Magnevist®
(gadopentetate dimeglumine 469.01 mg/mL)
INJECTION

PRECAUTIONS - General

Diagnostic procedures that involve the use of contrast agents should be carried out under direction of a physician with the prerequisite training and a thorough knowledge of the procedure to be performed.

In a patient with a history of grand mal seizures, MAGNEVIST® Injection was reported to induce such a seizure.

Since gadopentetate dimeglumine is cleared from the body by glomerular filtration, caution should be exercised in patients with severely impaired renal function.

The possibility of a reaction, including serious, life-threatening, fatal, anaphylactoid or cardiovascular reactions or other idiosyncratic reactions should always be considered (see ADVERSE REACTIONS) especially in those patients with a known clinical hypersensitivity.

Animal studies suggest that gadopentetate dimeglumine may alter red cell membrane morphology resulting in a slight degree of extravascular (splenic) hemolysis. In clinical trials 15-30% of the patients experienced an asymptomatic transient rise in serum iron. Serum bilirubin levels were slightly elevated in approximately 3.4% of patients. Levels generally returned to baseline within 24 to 48 hours. Hematocrit and red blood cell count were unaffected and liver enzymes were not elevated in these patients. While the effects of gadopentetate dimeglumine on serum iron and bilirubin have not been associated with clinical manifestations, the effect of the drug in patients with hepatic disease is not known and caution is therefore advised.

When MAGNEVIST® Injection is to be injected using plastic disposable syringes, the contrast medium should be drawn into the syringe and used immediately.

If nondisposable equipment is used, scrupulous care should be taken to prevent residual contamination with traces of cleansing agents.

Repeat Procedures: If in the clinical judgment of the physician sequential or repeat examinations are required, a suitable interval of time between administrations should be observed to allow for normal clearance of the drug from the body.

Information for Patients:

Patients receiving MAGNEVIST® Injection should be instructed to:

1. Inform your physician if you are pregnant or breast feeding.
2. Inform your physician if you have anemia or any diseases that affect red blood cells.

LABORATORY TEST FINDINGS

Transitory changes in serum iron and bilirubin levels have been reported in patients with normal and abnormal liver function (See PRECAUTIONS - General).

CARCINOGENESIS, MUTAGENESIS, AND IMPAIRMENT OF FERTILITY

No animal studies have been performed to evaluate the carcinogenic potential of gadopentetate dimeglumine.

Gadopentetate dimeglumine did not evoke any evidence of mutagenic potential in the Ames test (histidine-dependent *Salmonella typhimurium*) nor in a reverse mutation assay using tryptophan-dependent *Escherichia coli*. Gadopentetate dimeglumine did not induce a positive response in the (C3H 10T1/2) mouse embryo fibroblast cellular transformation assay, nor did it induce unscheduled DNA repair synthesis in primary cultures of rat hepatocytes at concentrations up to 5000 μg/mL. However, the drug did show some evidence of mutagenic potential *in vivo* in the mouse dominant lethal assay at doses of 6 mmol/kg, but did not show any such potential in the mouse and dog micronucleus tests at intravenous doses of 9 mmol/kg and 2.5 mmol/kg, respectively.

The results of a reproductive study in rats showed that gadopentetate dimeglumine when administered in daily doses of 0.1-2.5 mmol/kg, did not cause a significant change in the pregnancy rate in comparison to a control group. However, suppression of body weight gain and food consumption and a decrease in the mean weights of testis and epididymis occurred in male rats at the 2.5 mmol/kg dose. In female rats a decrease in the number of corpora lutea at the 0.1 mmol/kg dose and the suppression of body weight gain and food consumption at the 2.5 mmol/kg dose were observed.

In a separate experiment, 16 daily intravenous injections were administered to male rats. At a dose of 5 mmol/kg of gadopentetate dimeglumine, spermatogenic cell atrophy was observed. This atrophy was not reversed within a 16-day observation period following the discontinuation of the drug. This effect was not observed at a dose of 2.5 mmol/kg.

PREGNANCY CATEGORY C.

Gadopentetate dimeglumine has been shown to retard development slightly in rats when given in doses 2.5 times the human dose, and in rabbits when given in doses of 7.5 and 12.5 times the human dose. The drug did not exhibit this effect in rabbits when given in doses 2.5 times the human dose. No congenital anomalies were noted in either species.

There are no adequate and well-controlled studies in pregnant women. MAGNEVIST® Injection should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

NURSING MOTHERS

C^{14} labelled gadopentetate dimeglumine was administered intravenously to lactating rats at a dose of 0.5 mmol/kg. Less than 0.2% of the total dose was transferred to the neonate via the milk during the 24-hour evaluation period. It is not known to what extent MAGNEVIST® Injection is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when the drug is administered to a nursing mother and consideration should be given to temporarily discontinuing nursing.

PEDIATRIC USE

Safety and efficacy in children under the age of 2 years have not been established. (See Indications and Usage and Dosage and Administration sections).

ADVERSE REACTIONS

The most commonly noted adverse experience is headache with an incidence of 8.7%. The majority of headaches are transient and of mild to moderate severity. In 42.3% of the cases it was felt that the headaches were not related to MAGNEVIST® Injection. Injection site coldness/localized coldness is the second most common adverse experience at 4.8%. Nausea occurs in 3.2% of the patients.

Localized pain, vomiting, paresthesia, dizziness and localized warmth occur in less than 2% of the patients.

The following additional adverse events occur in less than 1% of the patients:

Body as a Whole: Injection site symptoms, namely, pain, warmth, burning; localized burning sensation, substernal chest pain, fever, weakness, generalized coldness, localized edema, tiredness, chest tightness, regional lymphangitis, anaphylactoid reactions (characterized by cardiovascular, respiratory and cutaneous symptoms).
Cardiovascular: Hypotension, vasodilation, pallor, non-specific ECG changes, angina pectoris, phlebitis.
Digestive: Gastrointestinal distress, stomach pain, teeth pain, increased salivation.
Nervous System: Agitation, thirst, convulsions (including grand mal).
Respiratory System: Throat irritation, rhinorrhea, sneezing, dyspnea, wheezing, laryngismus, cough.
Skin: Rash, sweating, pruritus, urticaria (hives).
Special Senses: Tinnitus, conjunctivitis, visual field defect, taste abnormality, dry mouth, lacrimation disorder (tearing), eye irritation.
Laboratory: Transient elevation of serum transaminases.

The following other adverse events were reported. A causal relationship has neither been established nor refuted.

Body as a Whole: Back pain, pain, generalized warmth.
Cardiovascular: Hypertension, tachycardia, migraine, syncope, death related to myocardial infarction or other undetermined causes.
Digestive: Constipation, diarrhea.
Nervous System: Anxiety, anorexia, nystagmus, drowsiness, diplopia, stupor.
Skin: Facial edema, erythema multiforme, epidermal necrolysis.
Special Senses: Eye pain, ear pain.
Data from foreign studies did not reveal any additional adverse experiences.

OVERDOSAGE

The LD_{50} of intravenously administered gadopentetate dimeglumine injection in mice is 5-12.5 mmol/kg and in rats it is 10-15 mmol/kg. The LD_{50} of intravenously administered MAGNEVIST® Injection in dogs is greater than 6 mmol/kg.

Clinical consequences of overdose with MAGNEVIST® Injection have not been reported.

DOSAGE AND ADMINISTRATION

The recommended dosage of MAGNEVIST® Injection is 0.2 mL/kg (0.1 mmol/kg), administered intravenously, at a rate not to exceed 10 mL per minute. More rapid injection rates may be associated with nausea. The maximum total dose is 20 mL. Any unused portion must be discarded.

DOSAGE CHART

Body Weight (kg)	Dose in mL	Approx Duration of Injection in Seconds
10	2.0	20
20	4.0	30
30	6.0	40
40	8.0	50
50	10.0	60
60	12.0	70
70	14.0	80
80	16.0	95
90	18.0	110
100	20.0	120

To ensure complete injection of the contrast medium, the injection should be followed by a 5-mL normal saline flush. The imaging procedure should be completed within 1 hour of injection of MAGNEVIST® Injection.

Parenteral products should be inspected visually for particulate matter and discoloration prior to administration, whenever solution and container permit.

For full prescribing information, see package insert.

Caution: Federal Law Prohibits Dispensing Without Prescription.

N-Methyl-D-Aspartate Antagonists in the Treatment of Parkinson's Disease

J. Timothy Greenamyre, MD, PhD, Christopher F. O'Brien, MD

• Current long-term treatment of Parkinson's disease is inadequate, and improved symptomatic and neuroprotective therapies are needed. Recent interest has focused on the use of antagonists of the *N*-methyl-D-aspartate (NMDA) subtype of glutamate receptor in Parkinson's disease. Abnormally increased activity of the subthalamic nucleus is postulated to play a central pathophysiological role in the signs of Parkinson's disease, and NMDA antagonists may provide a means of decreasing this activity selectively. Like dopaminergic agonists, NMDA antagonists can reverse the akinesia and rigidity associated with monoamine depletion or neuroleptic-induced catalepsy. Very low doses of NMDA antagonists markedly potentiate the therapeutic effects of dopaminergic agonists. There is evidence that the beneficial effects of anticholinergic drugs and amantadine may be mediated, in part, by NMDA receptor blockade. Moreover, NMDA antagonists provide profound protection of dopaminergic neurons of the substantia nigra in the MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine) and methamphetamine models of Parkinson's disease. The clinical use of NMDA antagonists may prove useful in Parkinson's disease to treat symptoms and retard disease progression.

(*Arch Neurol.* 1991;48:977-981)

Long-term treatment of Parkinson's disease is inadequate and, despite current therapies, the disease progresses. The initially gratifying response to therapy is eventually replaced by a fluctuating response to levodopa and other dopaminergic agents. Within 5 years of diagnosis, most patients receiving levodopa therapy experience fluctuations in their motor function ranging from periods of good mobility, often accompanied by dyskinesias, to periods of relative immobility.[1,2] As the disease progresses and the "therapeutic window" for dopaminergic agents narrows, motor fluctuations become less predictable and more difficult to manage. Clearly, improved therapies are needed.

The conventional strategy for therapeutic intervention is the rational development of drugs to provide more effective symptomatic relief. For a century, the only effective treatment of Parkinson's disease was anticholinergic therapy, but the mechanism by which these drugs produced a beneficial response was unknown.[3] The first rational treatment, levodopa,[4] was developed after the demonstration of a severe dopamine deficiency in Parkinson's disease.[5] Subsequent efforts at drug design have focused primarily on dopamine receptor agonists[6]; however, as the anatomical, biochemical, and pharmacological features of neurotransmitter interactions in the basal ganglia are elucidated, it is likely that drugs targeted at other transmitter systems and receptors may also prove useful clinically.

Although the ultimate cause of Parkinson's disease is not known, a second strategy for pharmacological intervention is the use of neuroprotective agents to retard neuronal damage and death. Slowing the rate of disease progression would be expected to forestall, or even prevent, the emergence of disabling motor fluctuations. This strategy was central to the DATATOP (*D*eprenyl *a*nd *T*ocopherol *A*ntioxidative *T*herapy *o*f *P*arkinsonism) study, which showed an apparent slowing of the natural course of Parkinson's disease in patients treated with deprenyl.[7] Although the DATATOP results are preliminary, the goal of developing protective therapies in Parkinson's disease is novel and important, and it needs further exploration.

A growing body of evidence suggests that modulation of the activity of the major excitatory neurotransmitter, glutamate, may be beneficial in Parkinson's disease (Table). Overactivity of the subthalamic nucleus, thought to play a crucial role in parkinsonian signs, may be reduced by glutamate receptor antagonists. In some cases, dopamine receptor agonists and glutamate receptor antagonists have similar actions at both the biochemical and behavioral levels. Additionally, the beneficial effects of "anticholinergic" drugs and amantadine may be due, in part, to their blockade of glutamate receptors. Finally, glutamate receptor antagonists confer a profound neuroprotective effect in animal models of Parkinson's disease. In this article, the evidence suggesting a role for glutamate receptor antagonists in the treatment of Parkinson's disease is reviewed.

THERAPEUTIC BLOCKADE OF SUBTHALAMIC OUTPUT

Degeneration of dopaminergic neurons projecting from the substantia nigra pars compacta (SNc) to the striatum results in increased activity of the striatal neurons projecting to the lateral globus pallidus (LGP), and decreased activity of striatal neurons projecting to the medial globus pallidus (MGP) and the substantia nigra pars reticulata (SNr).[8,9] These striatal efferent pathways γ-aminobutyric acid (GABA) and are inhibitory, so the activity of the LGP projection to the subthalamic nucleus (STN) is reduced, and the activities of the MGP and SNr pathways to the thalamus are increased.[10,11] The reduced activity of an inhibitory GABAergic pathway to the STN disinhibits STN neurons and causes them to be more active. The enhanced activity of the excitatory glutamatergic STN projections to MGP and SNr further increases the activity of GABAergic MGP and SNr neurons.[10,11] The net result is increased activity of inhibitory neurons in the output nuclei (MGP and SNr) of the basal ganglia and, consequently, reduced activity of thalamocortical neurons. It has

Rationale for the Use of NMDA Antagonists in Parkinson's Disease*

- Pharmacological blockade of the abnormally increased activity of subthalamic output
- NMDA antagonists enhance the release and turnover of striatal dopamine in vivo
- NMDA antagonists reverse the akinesia and rigidity associated with monamine depletion or neuroleptic-induced catalepsy
- Subthreshold doses of NMDA antagonists synergize with dopaminergic agonists and anticholinergic drugs
- NMDA receptor blockade may account for some of the antiparkinsonian effects of amantadine and the anticholinergic drugs
- NMDA antagonists protect nigral neurons from death in the methamphetamine and MPTP models of Parkinson's disease

*NMDA indicates *N*-methyl-D-aspartate; MPTP, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine.

been suggested that the resultant reduced thalamocortical activity accounts for parkinsonian signs.[8,10-12]

In this model of basal ganglia function, overactivity of the STN projections is postulated to play a central role in the clinical manifestations of Parkinson's disease.[8,10-12] Increased activity of STN neurons has been reported in monkeys treated with 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP).[8,12] Inactivation of the STN in parkinsonian animals would be expected to reduce activity of the MGP and SNr, thereby increasing thalamocortical activity, and producing clinical improvement. In fact, ablation of the STN in MPTP-treated monkeys markedly reduces parkinsonian signs of akinesia, rigidity and tremor, as predicted by the model.[13]

Because the STN projection is glutamatergic,[14,15] pharmacological "inactivation" of this pathway may be possible with glutamate-receptor antagonists. Several distinct glutamate receptors have been identified and have been named for *N*-methyl-D-aspartate (NMDA), kainate, and quisqualate, which are the most selective agonists at each receptor type.[16,17] Of these, the NMDA receptor is the best characterized and highly specific antagonists are available. There are moderate numbers of NMDA receptors in the entopeduncular nucleus, MGP, and STN.[18] Injection of NMDA receptor antagonists into the entopeduncular nucleus (the rodent analog of MGP) or into the SNr of monoamine-depleted rats potently reverses akinesia and rigidity.[19] The STN itself receives prominent excitatory input (probably glutamatergic) from neocortex,[20] and NMDA receptors are involved in synaptic activation of STN.[21] As anticipated, the akinesia and rigidity associated with monoamine-depletion are also reversed by injection of NMDA receptor antagonists into the STN.[19]

Would systemic administration of NMDA receptor antagonists have beneficial therapeutic effects, or are these drugs only helpful when injected into discrete nuclei? The STN output to MGP and SNr is the only glutamatergic pathway that is thought to have abnormally increased activity in Parkinson's disease.[8,10-12] It is conceivable that low doses of NMDA antagonists could suppress selectively the overactivity of MGP and SNr neurons without producing the deleterious side effects expected of massive blockade of NMDA receptors elsewhere in the brain. Consistent with this hypothesis, it has been shown that systemic administration of MK-801, a noncompetitive NMDA receptor antagonist, causes a pronounced locomotor stimulation in mice or rats depleted of monoamines.[19,22] Moreover, after monoamine depletion, there is a marked synergism such that a very low systemic dose of a competitive or noncompetitive NMDA antagonist, when combined with either a muscarinic cholinergic antagonist or a subthreshold dose of levodopa, apomorphine, or SKF38393 (a selective dopamine D_1 receptor agonist), stimulates motor activity effectively.[19,23]

In contrast to these studies, however, there is a preliminary report indicating that when MK-801 was administered to a single MPTP-treated monkey, it was without therapeutic benefit.[24] The therapeutic index of MK-801 is very low, and the fact that the treated monkey was described as having "marked unresponsiveness to environmental stimuli" suggests that anesthetic doses of the drug may have been employed.[24] Additional studies using a variety of NMDA antagonists in MPTP-treated monkeys will clarify this discrepancy.

SIMILARITY OF ACTION OF DOPAMINERGIC AGONISTS AND NMDA ANTAGONISTS

Biochemical Effects

Stimulation of dopamine D_1 receptors activates adenyl cyclase and results in increased intracellular levels of cAMP.[25] This, in turn, activates cAMP-dependent protein kinase.[26] One of the substrates for this kinase is DARPP-32, a dopamine- and cAMP-regulated phosphoprotein that is enriched in striatonigral neurons.[27] Once phosphorylated, DARPP-32 becomes a potent inhibitor of protein phosphatase-1, and it has been hypothesized that the function of phospho-DARPP-32 may be to prevent dephosphorylation of other substrates in nigrostriatal neurons.[28] Activation of NMDA receptors results in dephosphorylation of DARPP-32 and, in this way, antagonizes the action of dopamine.[29,30] *N*-methyl-D-aspartate receptor antagonists prevent glutamate-induced dephosphorylation of DARPP-32 and, therefore, facilitate dopaminergic function.[29,30]

Behavioral Effects

Catalepsy (postural rigidity) can be induced in rats by administration of neuroleptics and has been used by some investigators as a model of Parkinson's disease. Neuroleptic-induced catalepsy is reversed by either dopaminergic agonists or competitive and noncompetitive NMDA receptor antagonists.[31,32] Dopaminergic agonists and NMDA receptor antagonists may also have similar effects in drug discrimination studies. Rats trained to discriminate the selective D_2 agonist, quinpirole, from saline cross-generalize to MK-801 injected intraperitoneally (D. Cory-Slechta, PhD, written communication, 1990).

The mechanism by which NMDA receptor antagonists produce behavioral effects similar to those of dopamine agonists is unknown and needs to be investigated. Conceivably, it might be related to intracellular biochemical events such as those mediated by DARPP-32.[29,30] It has also been reported by several investigators that NMDA receptor antagonists increase striatal dopamine release and turnover in vivo.[33-35] Either of these potential mechanisms would likely be beneficial in Parkinson's disease.

CURRENTLY USED MEDICATIONS AS NMDA ANTAGONISTS

It appears certain that blockade of central muscarinic receptors plays a role in the beneficial effects of anticholinergic drugs. For example, administration of a centrally active cholinesterase inhibitor increases parkinsonian symptoms, and this can be blocked by anticholinergic medications.[36] On the other hand, the doses and serum levels of these drugs appear to be excessive relative to the number and affinity of muscarinic receptors in the brain. With a total daily dose of trihexyphenidyl of only 5 mg, *trough* serum levels as high as 200 nmol/L have been reported, and trough levels increase in proportion to daily dose.[37] Peak levels of trihexyphenidyl may be as high as 1000 nmol/L (1 μmol/L) after a single 10-mg dose.[38] In dystonic patients treated with higher doses of trihexyphenidyl, trough levels may approach 2000 nmol/L (2 μmol/L).[37] As judged by positron emission tomographic scanning studies employing labeled anticholinergic drugs, these compounds penetrate the blood brain barrier easily, and it is expected that serum levels and unbound extracellular central nervous system levels would be about equivalent (K. Frey, MD, PhD, oral communication, 1990). Because the affinity of muscarinic cholinergic receptors for trihexyphenidyl is 1 nmol/L,[39] it appears that the receptors may be saturated with drug at low to moderate clinical doses.

Anticholinergic drugs are also noncompetitive antagonists of the NMDA receptor. Trihexyphenidyl (Artane), ethopropazine (Parsidol), procyclidine (Kemadrin), and diphenhydramine (Benadryl) each interact with the NMDA receptor, apparently acting at the ion channel.[40] It has been shown that procyclidine and ethopropazine compete for MK-801 binding with inhibition constants in the low micromolar range.[40] As noted above, anticholinergic drug levels in the brain may approach concentrations at which they would be expected to interact significantly with NMDA receptors. This raises the possibility that blockade of NMDA receptors by anticholinergic drugs may be important in their beneficial antiparkinsonian effects.

Other drugs used commonly in the treatment of Parkinson's disease may also have NMDA receptor antagonist properties. Memantine (1-amino-3,5-dimethyl adamantane), a dimethyl congener of amantadine, is used to treat Parkinson's disease in Europe. Like dopaminergic agonists and NMDA antagonists, memantine reverses neuroleptic-induced catalepsy.[31] Using patch clamp techniques, it has been shown that NMDA receptor ion channel currents are blocked by memantine.[41] At therapeutic concentrations, memantine also competes for MK-801 binding.[42] Amantadine (1-amino adamantane), a more commonly used adamantane derivative, modulates the sensitivity of NMDA receptor ion channel binding sites as measured by phencyclidine binding.[43] Together, these findings suggest that the therapeutic benefits of these drugs may be mediated, in part, by NMDA receptor blockade.

OTHER POTENTIAL SYMPTOMATIC BENEFITS OF NMDA ANTAGONISTS

The effects of other antiparkinsonian medications may be potentiated by NMDA receptor antagonists. When MK-801 is administered to monoamine-depleted mice in doses that are without behavioral effect, addition of an anticholinergic drug causes a marked locomotor stimulation.[23] Similarly, when subthreshold doses of MK-801 and apomorphine are given in combination to monoamine-depleted mice, there is a synergistic response and motor activity increases.[23] Most recently, it has been demonstrated that extremely low doses of competitive or noncompetitive NMDA antagonists, themselves without motor effects, shift the dose-response curve of levodopa to the left in rats depleted of monoamines.[19] In the clinical setting, low-dose NMDA antagonist therapy might provide a means of lowering the doses of other medications, or of increasing their efficacy. If oxidative products of dopamine play a role in nigral cell death,[44] low-dose NMDA antagonists may allow clinicians to decrease levodopa doses and, thereby, diminish the potential for oxidative damage.

Just as anticholinergic drugs can act as NMDA antagonists, NMDA receptor antagonists can function as "anticholinergic" agents. In the striatum, activation of NMDA receptors causes release of acetylcholine, and antagonists can effectively inhibit this release.[45,46] Decreased release of striatal acetylcholine may complement and potentiate the anticholinergic effects of direct muscarinic antagonists and provides another mechanism, by which NMDA antagonists might augment antiparkinsonian therapy.

N-methyl-D-aspartate receptor antagonists may also help to prevent or minimize the unpredictable and sometimes disabling dyskinesias associated with chronic dopaminergic agonist therapy. It has been suggested that dopamine receptor sensitization may be involved in the pathophysiology of the hyperkinetic movements that begin after long-term treatment of Parkinson's disease.[1,47] In 6-hydroxydopamine–lesioned rats, MK-801 prevents the receptor sensitization that occurs with chronic D_1 agonist treatment.[48] Thus, if receptor sensitization is important in the development of dyskinesias, NMDA antagonists may be useful adjuncts to dopaminergic agonist therapy.

NMDA ANTAGONISTS AS NEUROPROTECTIVE AGENTS IN PARKINSON'S DISEASE

Excitotoxicity mediated by activation of NMDA receptors has been implicated in the pathogenesis of chronic neurodegenerative disorders, including Huntington's disease,[49,50] amyotrophic lateral sclerosis,[51] olivopontocerebellar atrophy,[52] and Alzheimer's disease.[53,54] The ion channel of the NMDA receptor complex is gated (blocked) by magnesium in a voltage-dependent fashion.[55] When a neuron is depolarized for any reason, or if it is unable to maintain its membrane potential, the magnesium blockade is lifted and the NMDA receptor can be activated. Glucose metabolism and adenosine triphosphate production via oxidative metabolism are necessary to generate a resting membrane potential sufficient to maintain the voltage-dependent magnesium blockade of the NMDA receptor ion channel[56]; as intracellular adenosine triphosphate levels decrease, there is a concomitant decline in membrane potential. In this way, neurons that are compromised by some other process, such as defective mitochondrial energy metabolism, would be rendered more vulnerable to NMDA receptor–mediated toxicity.[57] In such compromised neurons, normal concentrations of glutamate may become lethal, and excitotoxicity might simply be the final common pathway to cell death. (Roger Albin, MD [written communication, 1990], has termed this the "weak excitotoxic hypothesis.") In this regard, the recently described defect in complex I of the mitochondrial electron transport chain in Parkinson's disease may be important.[58-60] This defect would be expected to increase the potential for excitotoxic cell damage both by increasing levels of glutamate and by indirectly reducing magnesium blockade of the ion channel.

N-methyl-D-aspartate receptor antagonists provide almost complete protection against methamphetamine-induced toxicity to the nigrostriatal dopamine pathway, a model of Parkinson's disease.[61] The anatomical site at which NMDA antagonists confer protection is unknown. More recently, it has also been shown that competitive and noncompetitive NMDA antagonists protect against MPP^+ toxicity if these agents are given throughout the period in which MPP^+ is present in the brain.[62] The NMDA antagonists are protective when administered systemically or by direct injection into the substantia nigra, suggesting that it is the substantia nigra that is the site of action of these drugs. The substantia nigra receives glutamatergic innervation from a frontal cortex and contains a moderate number of NMDA receptors.[18] The toxin MPP^+ is believed to act by specifically inhibiting complex I of the mitochondrial electron transport chain,[63] thereby creating a bioenergetic defect in nigral neurons. It seems likely that NMDA antagonists are conferring protection simply by blocking the excitotoxic final common pathway to cell death and allowing neurons to survive until the toxin (MPP^+) is no longer present. If environmental toxins or bioenergetic defects play roles in the cause of Parkinson's disease, NMDA receptor antagonists may provide a means of retarding disease progression.

POTENTIAL PROBLEMS AND FUTURE DIRECTIONS

Does the fact that certain currently used medications may have NMDA antagonist properties mean that specific NMDA antagonists will not improve the treatment of Parkinson's disease? Amantadine, memantine, and the anticholinergic agents are weak and nonspecific NMDA antagonists, and they all have effects on other neurotransmitter systems that produce dose-limiting side effects. For example, in addition to its effects on the dopamine system, amantadine has variable effects on norepinephrine, serotonin, GABA, and acetylcholine that certainly limit its use as an NMDA antagonist.[64] The anticholinergic drugs probably saturate the brain's muscarinic receptors before exerting a significant blockade of the NMDA receptor. Because the drugs used currently for Parkinson's disease interact with numerous transmitter systems, including the glutamatergic system, it is likely that intolerable side effects develop before there is significant NMDA receptor blockade. This may explain why treatment with amantadine and the anticholinergic drugs does not appear to slow disease progression. Thus, there is reason to be optimistic that *specific* NMDA antagonists may prove to be useful clinically.

Treatment of patients with NMDA receptor antagonists, however, may possibly be associated with significant side effects. Noncompetitive antagonists acting at the receptor ion channel may have psychotomimetic or dissociative anesthetic properties similar to phencyclidine (PCP) and ketamine.[65] Because the NMDA receptor is also apparently important in learning and memory functions,[66] antagonists might cause cognitive impairment. On the other hand, the potential for side effects is likely to be dependent on the type of antagonist used, and the incidence of side effects would be expected to be dose dependent. Competitive antagonists appear to have less psychotomimetic potential than noncompetitive antagonists,[67] and even MK-801, a potent noncompetitive blocker, did not produce psychosis when administered to humans with epilepsy.[68] Moreover, animal studies indicate that extremely low doses of NMDA antagonists may produce a potent and clinically useful synergy with commonly used anticholinergic and dopaminergic agonist drugs.[19,23] Thus, it may be possible to use selective NMDA antagonists therapeutically without encountering intolerable side effects.

Both basic and preclinical studies must be performed before NMDA receptor antagonists are used in patients with Parkinson's disease. Although some investigators have found no NMDA receptor changes with chronic in vivo antagonist treatment (A. B. Young, MD, PhD, oral communication, 1990), it has been reported that treatment of primary neuronal cultures with competitive antagonists may increase the number of MK-801 binding sites (P. Molinoff, MD, oral communication, 1990). Because the clinical impact of increased numbers of NMDA receptors might be enhanced excitotoxic potential as well as symptomatic decline, the chronic effects of antagonists on the NMDA receptor complex must be defined unambiguously.

Administration of both competitive and noncompetitive NMDA antagonists has been associated with acute, reversible vacuolization in certain neurons of the cingulate and retrosplenial cortex in rats,[69] but the vacuolization subsides within 24 to 48 hours. This phenomenon appears to be self-limited, its functional significance is not clear,[70] and it can be prevented by co-administration of anticholinergic agents.[71] Despite the apparent benign nature of these changes, the issue of antagonist-associated vacuolization warrants further investigation prior to initiation of large-scale clinical trials.

It will be of interest to examine whether the increased activity of the subthalamic nucleus results in significant regulatory changes in glutamate receptors in MGP and SNr of MPTP-treated monkeys and patients with Parkinson's disease. Receptor down-regulation might alter the effectiveness of antagonist drugs. The mechanisms of interaction of anticholinergic drugs and amantadine with the NMDA receptor/ion channel complex remain to be explored in detail, and it would be useful to assess drug levels in cerebrospinal fluid of patients treated with these agents. At the preclinical level, it will be important to evaluate the efficacy of a variety of competitive and noncompetitive NMDA antagonists in reducing parkinsonian symptoms in MPTP-treated monkeys prior to beginning human trials. Whether low doses of NMDA antagonists produce synergistic effects with anticholinergics and dopaminergic agonists in parkinsonian monkeys must also be determined. It will also be of interest to evaluate the antiparkinsonian efficacy of antagonists of non-NMDA glutamate receptors. Initial studies of a quisqualate receptor antagonist in MPTP-induced parkinsonian *Rhesus* monkeys indicate that this class of drug has potent and dramatic antiparkinsonian properties when administered systemically.[72]

CONCLUSION

More effective symptomatic and neuroprotective therapies are needed urgently for Parkinson's disease. This review of the current literature on NMDA receptor antagonists in relation to Parkinson's disease makes a strong case for the use of these agents as an adjunct to current antiparkinsonian therapies. There are several reasons to believe that NMDA antagonists will provide symptomatic relief; in fact, the benefits derived from certain commonly used antiparkinsonian medications may be related to their ability to block NMDA receptors. Moreover, the neuroprotective properties of NMDA antagonists may allow clinicians to slow disease progression and delay disability by blocking the final common pathway that leads to nigral cell death. Although NMDA receptor antagonists may prove to be useful in this disorder, these drugs should be used in patients only after sufficient supportive data has been amassed from preclinical studies. It is hoped that this speculative review will stimulate research in this important area, and lead ultimately to better treatments for our patients with Parkinson's disease.

Medicolegal Forms with Legal Analysis

Medicolegal Forms with Legal Analysis is the ideal resource for assembling the legal pieces of your physician-patient relations. This **newly-revised** single volume contains virtually all the sample forms you need to develop customized medicolegal documentation for your medical practice.

Medicolegal Forms contains more than 80 sample forms developed by the AMA's Office of the General Counsel, along with discussions explaining the use and structure of the forms and case law citations.

Only *Medicolegal Forms with Legal Analysis* assembles this valuable information so conveniently for adaptation to individual practice situations.

Order your copy today; call toll-free **1-800-621-8335**

Observations

Unilateral Oculomotor Palsy and Bilateral Ptosis From Paramedian Midbrain Infarction

Grant T. Liu, MD; Enrique J. Carrazana, MD; Michael E. Charness, MD

• Lesions of the oculomotor fascicles are localized clinically by associated neurologic deficits. We present two patients with bilateral ptosis, unilateral paresis of all other muscles innervated by the oculomotor nerve, and sparing of the contralateral superior rectus muscle—findings suggesting a lesion of the proximal oculomotor fascicles and the central caudal subnucleus. To our knowledge, these are the first such cases with radiologic confirmation of a lesion within the dorsal, paramedian midbrain.

(*Arch Neurol.* 1991;48:983-986)

The oculomotor fascicles sweep ventrally and laterally from the oculomotor complex, pass through and medial to the red nucleus, and converge to exit the brain stem medial to the cerebral peduncles.[1] The clinical localization of lesions along the dorsal-ventral course of the oculomotor fascicles relies on associated neurologic findings. Damage to the ventral fascicles and the nearby cerebral peduncle causes ipsilateral third-nerve palsy and contralateral hemiparesis (Weber's syndrome).[2] Involvement of fascicles within the red nucleus leads to oculomotor palsy with contralateral involuntary movements (Benedikt's syndrome). Extension of such a lesion to the brachium conjunctivum produces additional contralateral ataxia (Claude's syndrome).[2] When sufficiently small, fascicular lesions can mimic complete or partial extra-axial third-nerve palsies.[3-8] Most of these have been located in the ventral midbrain, sparing the red nucleus and cerebral peduncles.

Small lesions of the proximal oculomotor fascicles have been reported only rarely.[5,8] Extension of such a lesion would involve the oculomotor subnuclei, the medial longitudinal fasciculus, and the mesencephalic reticular formation, causing ipsilateral oculomotor paresis and combinations of bilateral ptosis, bilateral superior rectus palsy, internuclear ophthalmoplegia, and lethargy.[2,9] We present two patients in whom focal infarction of the dorsal, paramedian midbrain led to a unique syndrome of pupil-sparing oculomotor palsy, lethargy, and bilateral ptosis, without affecting the contralateral superior rectus.

REPORT OF CASES

CASE 1.—A 46-year-old man developed double vision, bilateral ptosis, and lethargy immediately after a percutaneous transluminal coronary angioplasty for a complete right coronary artery occlusion. The patient had a history of recent myocardial infarction and hypercholesterolemia. Examination revealed pronounced bilateral ptosis in the setting of mild inattention and drowsiness. He could open his eyes only by lifting his lids manually. Visual acuity with correction was J1 OD and J2 OS. Visual fields by confrontation were normal. A small cotton wool exudate was noted along the superotemporal arcade in the left fundus. The pupils were equal, round, and reactive to light. In primary position the left eye deviated outward and downward. There was markedly decreased adduction and elevation of the left eye, and downward gaze was diminished on abduction. Attempted adduction of the left eye was accompanied by abducting nystagmus of the right eye. All movements of the right eye were normal. The remainder of his neurologic examination was normal. Magnetic resonance imaging (48 hours after the event) showed a small focus of increased T_2 signal in the left periaqueductal gray matter overlapping the left medial longitudinal fasciculus and caudal third-nerve nucleus (Fig 1). Two small punctate foci of increased T_2 signal were seen in the deep white matter of the right parietal and frontal lobes.

Over the first 48 hours right-sided ptosis resolved and left-sided ptosis improved considerably. Four days after the event he showed left-sided ptosis and diminished function of the left medial, superior, and inferior rectus and inferior oblique muscles with normal eye movements on the right side, except for abducting nystagmus on right horizontal gaze (Fig 2). Abduction and elevation of the left eye improved gradually over the subsequent week. After 6 weeks he had diplopia with occasional fused vision, mild left-sided ptosis with superior and medial rectus paresis, and a mild left-sided internuclear ophthalmoplegia. One month later transient diplopia was present only on sudden upgaze or with fatigue.

CASE 2.—A 31-year-old, previously healthy woman came to the hospital on January 16, 1990, complaining of sudden dizziness, difficulty seeing, and droopy eyelids. She smoked cigarettes and took oral contraceptives. Her blood pressure was 110/80 mm Hg and her heart rate was 60 beats per minute and regular. There were no heart murmurs. She was drowsy and inattentive but easily arousable. Her visual fields and acuity were normal. There was bilateral ptosis, which was worse on the left side. In primary position the left eye deviated outward and downward. Movements of the right eye were normal without abducting nystagmus. The left eye could not adduct and had only 30° of upward gaze and 45° of downward gaze. The pupils were 2 mm bilaterally and briskly reactive to light. She had mild right face and arm weakness, right-sided hyperreflexia, and truncal as well as gait ataxia.

The hematocrit, erythrocyte sedimentation rate, prothrombin time, partial thromboplastin time, and protein C, protein S, and antithrombin III levels were all normal. Results of laboratory studies revealed that the cerebrospinal fluid contained the following values: white blood cells, 0.006×10^9/L ($6/mm^3$) (lymphocytes, 0.91 [91]; mononuclear leukocytes, 0.05 [5]); red blood cells, 1×10^{12}/L ($1/mm^3$); glucose, 3.4 mmol/L (62 mg/dL); and protein 0.46 g/L (46 mg/dL). Rapid plasma reagin and antinuclear antibody were negative. Echocardiogram and 24-hour Holter monitor were normal. Magnetic resonance imaging 1 day after the event demonstrated three foci of increased T_2 signal in the left side of the midbrain: one located in the periaqueductal gray, one lateral to the red nucleus, and the third in the lateral portion of the cerebral penduncle (Fig 3). She was much more alert 2 days after admission. One week later, right-sided ptosis had resolved almost completely, left vertical gaze was improved, but she still showed mild left-sided ptosis and had only 10° of adduction.

COMMENT

Both patients had focal infarcts of the dorsal midbrain in the territory of the perforating paramedian branches of the proximal posterior cerebral artery (mesencephalic artery).[9,10] Biller and

colleagues[11] described a man who, like patient 1, developed a midbrain stroke after percutaneous transluminal coronary angioplasty. In Dawson and Fischer's[12] review of the neurologic complications of cardiac catheterization, five of 10 affected patients developed pontine and mesencephalic dysfunction, most likely as a result of artery-to-artery embolization. They postulated that catheter-induced trauma to the aorta or to the origin of the vertebral, inominate, or subclavian arteries might cause embolization preferentially to the vertebrobasilar circulation. Patient 1 had evidence for embolization in both the anterior and posterior circulations, involving the midbrain, retina, frontal lobe, and parietal lobe. Patient 2 likely suffered a thrombotic stroke as a consequence of her use of oral contraceptives and cigarettes, two additive risk factors for thrombosis.[13] The sudden onset of symptoms, improvement within days, and cerebrospinal fluid profile were consistent with infarction, and a search for other causes, short of angiography, was unrevealing.

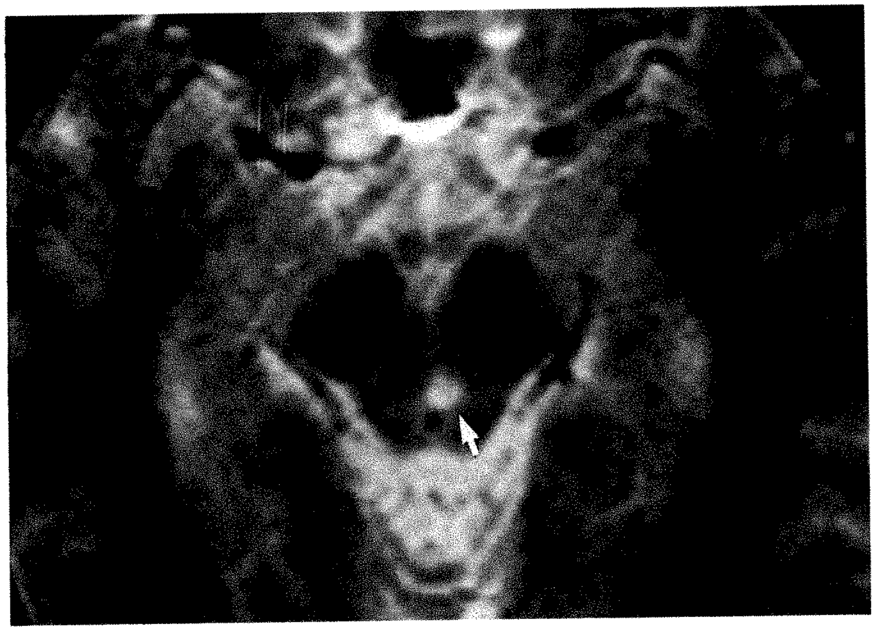

Fig 1.—Magnetic resonance imaging (TR = 2000 milliseconds, TE = 80 milliseconds) of the midbrain in patient 1, 2 days after his infarct. A single area of increased T_2 signal (arrow) is seen in the left paramedian midbrain involving the caudal portion of the oculomotor nucleus, the medial longitudinal fasciculus, and the periaqueductal gray matter.

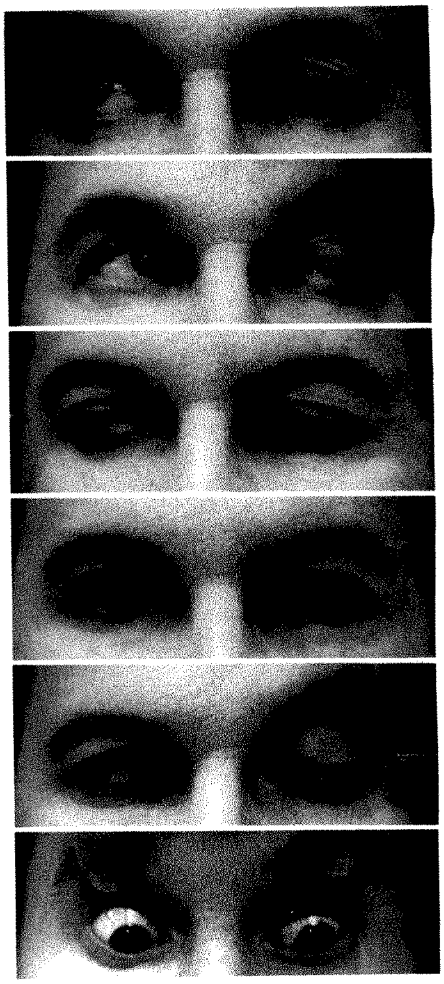

Fig 2.—Eye movements in patient 1, 4 days after his infarct. All of the abnormalities are in the left eye, including ptosis, diminished elevation on right and left upward gaze, and mildly diminished adduction and depression. By this time the right-sided ptosis had resolved and the left-sided ptosis, adduction, and depression had improved considerably.

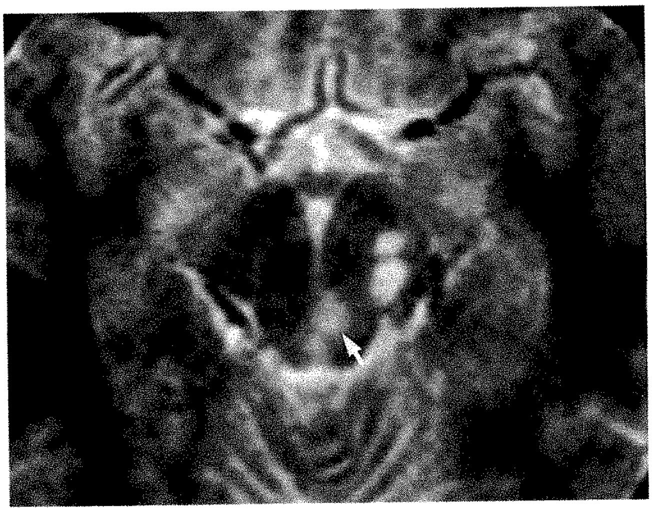

Fig 3.—Magnetic resonance imaging (TR = 2000 milliseconds; TE = 80 milliseconds) of the midbrain in patient 2, 1 day after her infarct. Three discrete regions of increased T_2 signal are seen. The left paramedian lesion (arrow) is nearly identical to that of patient 1 (Fig 2). Additional lesions in the left lateral peduncle and lateral to the red nucleus should spare the third-nerve fascicles, which course through and medial to the red nucleus before exiting the brain stem in the interpeduncular fossa.

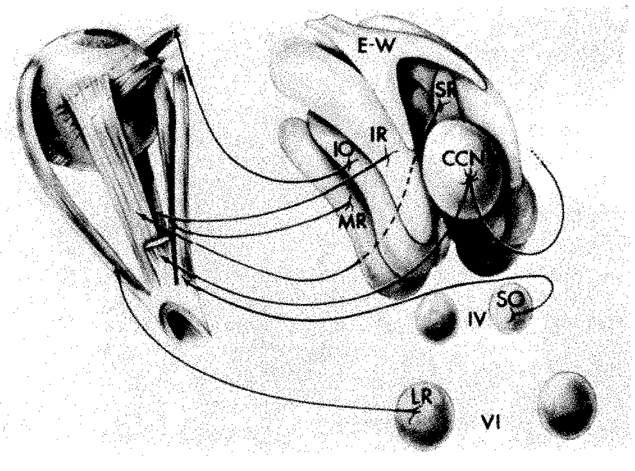

Fig 4.—Anatomy of the oculomotor complex, as proposed by Warwick.[14] The superior rectus (SR) muscle is innervated by a contralateral subnucleus. The central caudal nucleus (CCN) innervates both levator palpebrae muscles. The Edinger-Westphal subnucleus (E-W) and subnuclei for the inferior rectus (IR), inferior oblique (IO), and medial rectus (MR) muscle are arranged ipsilaterally. SO indicates superior oblique; LR, lateral rectus; and nuclei of the fourth (IV) and sixth (VI) cranial nerves (reproduced from reference 20 as modified from Warwick,[14] with permission from Wiley-Liss).

Ocular findings in these two patients were confined to extraocular muscles innervated by the left third nerve: superior, medial, and inferior rectus, inferior oblique, and levator palpebrae. In both cases, ptosis was bilateral and asymmetric, being worse ipsilateral to the ophthalmoparesis. The pupils were spared and all movements of the right eye were normal to bedside examination. (It is conceivable that minor involvement of the right superior rectus muscle might have been detected using more sensitive methods, such as Lancaster testing.) Within 1 week, both patients showed only left-sided abnormalities, including ptosis, decreased elevation, and impaired adduction, the latter due to an internuclear ophthalmoplegia in patient 1 and a medial rectus palsy in patient 2.

The selective involvement of oculomotor function and the relative paucity of additional neurologic signs suggests that both patients suffered small lesions of the paramedian midbrain. Bilateral ptosis is the hallmark of involvement of the central caudal subnucleus and localizes the lesions to the caudal oculomotor complex and its immediate vicinity.[2,14-17] The preservation of pupillary function implies sparing of the Edinger-Westphal complex and serves to delimit the dorsal and rostral extent of the nuclear lesion.[14] The internuclear ophthalmoplegia in patient 1 indicates involvement of the left medial longitudinal fasciculus, adjacent to the oculomotor complex, and drowsiness in both patients could be explained by transient disconnection of the midline midbrain reticular formation from the thalamus.[9]

This clinical neuroanatomic localization was confirmed by magnetic resonance imaging, which disclosed a small lesion in the dorsal paramedian midbrain in each patient. Although patient 2 had two additional lesions in the ventral midbrain, it is doubtful that these contributed significantly to her oculomotor deficit since both were lateral to the third-nerve fascicles.[17] The lesion involving the left cerebral peduncle likely explains her right hemiparesis, whereas that lateral to the left red nucleus could have caused her ataxia by interrupting fibers from the superior cerebellar peduncle in the dentatorubrothalamic tract.[18,19]

According to Warwick's[14] scheme for the subdivisions of the oculomotor nuclei, the midline central caudal nucleus supplies both levator palpebrae muscles, and each superior rectus muscle is innervated by a contralateral subnucleus (Fig 4). Ipsilateral subnuclei subserve the remaining extraocular muscles innervated by the third nerve and the parasympathetic pupillary constrictor fibers.[14,20] Bienfang[21] demonstrated that axons from each superior rectus subnucleus cross the midline and pass through the contralateral subnucleus before reaching the opposite third nerve. Unilateral lesions of the oculomotor complex should therefore cause bilateral ptosis, ipsilateral mydriasis, ipsilateral palsy of the medial rectus, inferior rectus, and inferior oblique muscles, and bilateral superior rectus palsy.[2,11,17,21-23]

A small number of patients have been described in whom dorsal paramedian midbrain lesions have caused bilateral ptosis and ipsilateral oculomotor paresis.[15,16,22-24] When present, involvement of the superior rectus has been either bilateral, from a nuclear lesion,[16,22,23] or contralateral, from a supranuclear lesion.[24] Our patients are unique because oculomotor paresis and bilateral ptosis were unaccompanied by significant involvement of the contralateral superior rectus muscle. Although Caplan[25] briefly mentioned two patients with bilateral ptosis, complete ophthalmoplegia on one side, and "(no) other signs of third nerve deficit" on the other side, there was neither radiologic nor pathologic confirmation of the suspected midbrain lesion.

How could a lesion of the dorsal paramedian midbrain produce bilateral ptosis and ipsilateral elevator palsy? The central caudal and superior rectus subnuclei are adjacent structures.[14] If the elevator palsy, like the bilateral ptosis, was caused by a nuclear lesion, then the superior rectus subnucleus would have to have been uncrossed, contradicting anatomic studies in several mammalian species.[14,21,26-28] More likely, the elevator palsy was supranuclear or infranuclear.

Ipsilateral[29] and contralateral[24,30] midbrain lesions have been reported to cause monocular, supranuclear paresis of elevation, presumably by interrupting axons from the rostral interstitial nucleus of the medial longitudinal fasciculus, which is believed to mediate upgaze.[29] However, in our patients, paresis of the superior rectus and inferior oblique muscles was distinguished by hypotropia in primary gaze, typically absent in a supranuclear lesion.[29] Hence, the most likely explanation for their ipsilateral elevator palsy is a lesion in the oculomotor fascicles. The pattern of recovery suggests that the major damage was infranuclear; contralateral ptosis resolved within a few days, leaving unilateral ptosis and ipsilateral elevator palsy (Fig 2). These findings support the proposal that axons destined for the superior rectus, inferior oblique, and levator palpebrae muscles segregate dorsolaterally within the oculomotor fascicles.[1,7,31]

Precise anatomic correlation of this oculomotor disorder ultimately requires postmortem examination. Nonetheless, the nearly identical clinical and magnetic resonance findings in these two patients delineate a new syndrome of the proximal oculomotor fascicles. The sudden onset of lethargy, bilateral ptosis, and ipsilateral third-nerve palsy, with sparing of the contralateral superior rectus should suggest a lesion of the dorsal paramedian midbrain, including the proximal oculomotor fascicles and the adjacent central caudal subnucleus.

We are grateful to Don Bienfang, MD, Brigham and Women's Hospital, Boston, Mass, for helpful discussions and critical review of the manuscript.

Marchiafava-Bignami Disease, Syndrome of Interhemispheric Disconnection, and Right-handed Agraphia in a Left-hander

A. Rosa, MD; M. Demiati, MD; L. Cartz, MD; J. P. Mizon, MD

• We present an original case of Marchiafava-Bignami disease in a 47-year-old left-handed alcoholic man. Computed tomography and magnetic resonance imaging demonstrated the typical lesion, a necrosis of the middle portion of the corpus callosum. Diagnosis may thus be established in the living. In our case, the course was not fatal, which, to our knowledge, has only been described in four other cases in the literature. Clinically, our patient demonstrated an interhemispheric disconnection syndrome. The striking feature is that some of the symptoms were on the side opposite of the one that has previously been described in the literature, eg, right-handed agraphia, while others were on the usual side, eg, left-handed anomia. We discuss cerebral dominance for speech and handedness in left-handers and come to the conclusion that our patient's clinical features can only be explained by right hemispheric dominance for handedness and bilateral hemispheric representation of speech.

(*Arch Neurol.* 1991;48:986-988)

Marchiafava-Bignami disease is an uncommon disorder associated with alcoholism, presumably of nutritional or metabolic origin. This disease is defined by its pathologic features, ie, a symmetrical demyelination of the middle portion of the corpus callosum, with or without necrosis. The clinical features of the disease are quite variable, and diagnosis was rarely made before postmortem examination until computed tomography and magnetic resonance imaging were introduced. In some cases, the diagnosis is suggested by a syndrome of interhemispheric disconnection.[1-4] The course of the disease is usually fatal, yet we found four cases of recovery in the literature.[3-6]

We report the case of a left-handed alcoholic patient with Marchiafava-Bignami disease. The patient recovered, and special testing revealed an interhemispheric disconnection syndrome characterized by right-handed agraphia and apraxia, a sign of the foreign hand on the right side, and left-handed anomia.

REPORT OF A CASE

A 54-year-old left-handed male alcoholic was found unconscious at his home and was admitted to the hospital. Since his wife had left home 8 weeks previously, he had eaten very little but had continued drinking. General physical examination revealed malnutrition. The patient was confused and disoriented as to time and space. Neurologic examination revealed ataxia and gegenhalten. The ankle reflexes were abolished. There was no motor or sensory deficit. Plantar reflexes were flexor. No ocular motor disturbances were noted. The results of routine laboratory tests were normal. A cranial computed tomographic scan with and without contrast medium showed abnormal hypodensity of the corpus callosum, extending from the genu to the splenium; there was no contrast enhancement. The patient received thiamine treatment, and within a week he had partially recovered: consciousness was normal, and the ataxia and gegenhalten had disappeared. Cranial magnetic resonance imaging was performed on day 15 (Fig 1). A low-signal intensity area was demonstrated in the corpus callosum, extending from the genu to the splenium in T_1-weighted images. In T_2-weighted images, the abnormal area was demonstrated as a high-intensity area, which extended beyond the corpus callosum into the hemispheric white substance of the frontal horns. Neuropsychological testing was performed; then the patient was transferred to a convalescence ward. Six months later, a second series of neuropsychological tests were performed. A detailed account of his cognitive deficits is given below. A new computed tomographic scan showed the same abnormalities. Cerebral blood flow studies were performed with technetium Tc 99m exametazime and the scintillation camera. Several areas of decreased perfusion were demonstrated: the posterior zone of the frontal lobe and the parietal lobe of the right hemisphere; the temporo-occipital area of the left hemisphere; and the right cerebellum hemisphere with cerebellum diaschisis.

NEUROPSYCHOLOGICAL FINDINGS

The patient was tested once he had recovered normal consciousness. The results were as follows:

1. Spontaneous speech was intact. Comprehension of verbal or written material was good. When asked to write, under dictation, spontaneously, or copying, the patient performed well with his left hand, but was unable to draw letters or words with his right hand (apraxic agraphia) (Fig 2). Drawing geometric figures was disturbed with both the left and the right hands (constructional apraxia).

Accepted for publication March 25, 1991.

Reprint requests to Service de Neurologie, Hôpital Nord, Place Victor Pauchet, BP 3006, 80030 Amiens, France (Dr Rosa).

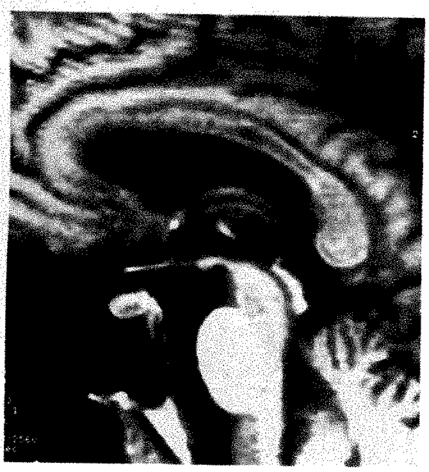

Fig 1.—Cranial magnetic resonance imaging scan. There was a low-signal intensity area in the corpus callosum in T_1-weighted images.

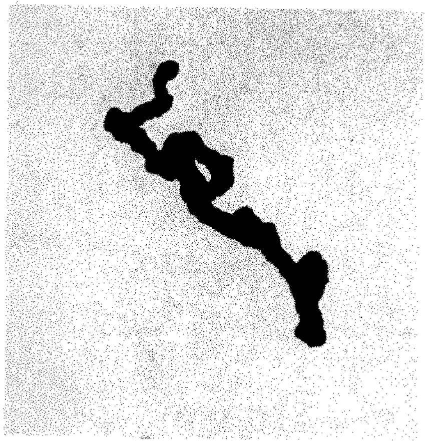

Fig 2.—Apraxic agraphia of the right hand. Writing under dictation: letter *b*.

2. Objects placed in the patient's right hand with his eyes closed were easily named. In the left hand, objects were not identified or with much delay, yet the patient could pick them out among others presented to him. In the same fashion, objects were named when presented in the right visual field, but not in the left. In the left visual field, the patient would deny seeing anything, yet he could correctly identify the objects among others.

3. Cooperation between the patient's left and right hands was disturbed, and the patient demonstrated diagnostic dyspraxia with an "alien" right hand. For instance, a scene observed during breakfast: if the right hand grasps a slice of bread, the patient is unable to release it, and when the left hand tries to take it from the right hand, there is an opposite movement of avoidance.

4. When asked to perform commands, the patient was disinclined to use his right hand, and when he did, responses were delayed. There was desynchronization of bilateral symmetrical movements, such as clapping hands together and on the lap.

5. As for performing to verbal command, responses were delayed or incorrect with right hand, although intent was good. The left hand performed well. Imitation was well done with both hands.

Six months later in follow-up, neuropsychological testing confirmed apraxic agraphia without aphasia in the right hand and bilateral constructional apraxia, which predominated in the right hand. There was persisting anomia (tactile aphasia) of the left hand. Tachistoscopy studies confirmed extinction of the left visual field. Dichotic testing revealed extinction of the left ear as well. Diagnostic dyspraxia and the right "alien hand" persisted. Crossed motor activities were impossible to perform, while imitation of ipsilateral activities was correct. There was right-hand ideomotor apraxia with neglect of the right hand.

COMMENT

The diagnosis of Marchiafava-Bignami disease in our patient was established on the association of a history of severe alcoholism, a clinical syndrome of interhemispheric disconnection, and neuroradiological images of extensive necrosis of the corpus callosum.

Course and Prognosis

Our patient did not die of Marchiafava-Bignami disease. Such a favorable clinical course is uncommon. We found four cases in the literature with a similar clinical course.[3-6]

Delangre et al[4] suggested that patients who survived had incomplete lesions with relative sparing of the superior commissure fibers, whereas lesions extending into the convolution white matter brought about death or severe dementia. This hypothesis was not confirmed by our case, in which magnetic resonance imaging demonstrated lesions that extended about the frontal horns and yet the clinical course was favorable.

Syndrome of Interhemispheric Disconnection and Agraphia

Bykov and Speransky[7] and Myers[8] demonstrated that corpus callosum is necessary for interhemispheric transfer of information in animals. The clinical aspects of postcallosotomy patients have been studied by Gazzaniga et al,[9] Geschwind and Kaplan,[10] and Bogen and Bogen[11], who showed that in animals and man, after section of the corpus callosum, the two isolated half brains behave independently, and that transfer of information is no longer possible between them.

Liepmann and Maas[12] were the first to point out that unilateral apraxia and agraphia in the absence of aphasia could be the signs of interhemispheric disconnection. This was confirmed by the studies of Gazzaniga et al[9] and Geschwind and Kaplan.[10] However, in these previous cases, agraphia and apraxia existed in the left hand, not in the right hand. In our case, agraphia and apraxia occurred in the right hand.

From a neuropsychological point of view, we found only four cases of right-handed agraphia without aphasia in the literature that could be explained by a interhemispheric disconnection. Unlike these four cases, our patient's lesion was limited to the corpus callosum.

Dejerine and Thomas[13] reported the case of a 49-year-old woman, left-handed except for writing, who presented with left hemiplegia and aphasia. By the end of her illness, 5 years later, she had recovered speech, and she had left hemiplegia with agraphia in the intact right hand. At postmortem, the brain showed no lesion in the left hemisphere, but a massive infarction was seen involving the right hemisphere and destroying the right side of the corpus callosum. In this case, there was agraphia in the hand opposite of an intact left hemisphere, which was capable of other language activities associated with a lesion of the right side of the corpus callosum.

The case of Nielsen[14] involved a left-handed man who wrote with his right hand. The patient abruptly developed weakness of his right leg and lost the ability to write with his right hand. Writing was still possible with his left hand. The clinical features suggest stroke in the anterior cerebral artery territory with lesions of the anterior four fifths of the corpus callosum.[15]

The patient of Botez and Crighel[16] was a 55-year-old woman. She was ambidextrous but wrote with the right hand, and her sister was left-handed. Embolism of the left middle cerebral artery caused receptive aphasia in this patient. After a rapid recovery, she developed a partial syndrome of interhemispheric disconnection consisting of writing disorders and tactile aphasia of the right hand, without agraphia of the left hand or aphasia. The evidence in this case suggested to the authors that their patient's representation of speech was bilateral and that of her writing was right hemispheric.

Heilman et al[15] described a left-handed 62-year-old man who developed a left hemiplegia without aphasia or alexia, and who lost ability to write with his right hand. He was right-handed for writing and one of his brothers was left-handed. He also showed severe right apraxia and extinction of the left side on testing with simultaneous auditory, somesthetic, and visual stimuli. These symptoms suggested a partial syndrome of interhemispheric disconnection. Analysis of this case suggested to the authors the presence of language dominance in the left hemisphere and dominance for handedness in the right one.

Another particularity in the interhemispheric disconnection syndrome of our patient is that the "sign of the foreign hand" affected the right side, not the left. This sign was described by Brion and Jedynak[17]: the patient complains that his hand does not obey and has difficulties recognizing his hand as being his own. When both hands are held behind his back, "the patient is unable to tell who the hand belongs to although he is perfectly aware of the presence of another hand in his own." This sign is not constantly present in the syndrome of interhemispheric disconnection, but when it exists, it is very important for diagnosis. It has been described on the left side or bilaterally. In our case, the sign affected the right side only, which, we believe, has not previously been described in the literature.

Cerebral Dominance

Several authors have studied the problem of cerebral dominance. Botez[18] distinguished three types: (1) an absolute cerebral dominance of the left hemisphere in right-handed subjects without family history of left-handedness; (2) a bilateral cerebral dominance in right-handed subjects with familial left-handedness, in left-handed subjects, and in ambidextrous subjects; and (3) a dissociated cerebral dominance in some subjects who have one of the speech functions located in one hemisphere and the remaining functions in the other.

Liepmann[19] suggested that manual dominance reflects the ability of one hemisphere to learn motor tasks more promptly than the other. According to this hypothesis, in some people, language dominance could be in one hemisphere and dominance of handedness in the other.

In their study of agraphia and apraxia in a left-hander, Heilman et al[15] suggested that a left-hander who is right-brain dominant for motor control may be either right brained or left brained for speech dominance. If a patient is right brained for both complex motor sequence learning and speech, and writes with the right hand, a callosal lesion should produce right-sided agraphia and apraxia but no left-sided agraphia; if the patient is right brained for handedness and left brained for speech, and writes with the right hand, a callosal lesion should produce bilateral agraphia, apraxic agraphia in the right hand, and aphasic agraphia with ideomotor apraxia in the left hand. They added that their conclusions would be modified if, after the callosal lesion, the patient could shift to the other hemisphere for speech or motor control.

In our case, left-handed anomia and extinction of audition of the left ear suggest left hemisphere dominance for speech, while apraxic agraphia and ideomotor apraxia predominating on the right side suggest right hemisphere dominance for handedness. The fact that, instead of bilateral agraphia, our patient showed only apraxic agraphia of the right hand can be explained by two hypotheses: either there was transfer of dominance from one hemisphere to the other after the onset of the callosal lesion, as suggested by Heilman et al,[15] or the patient had bilateral cerebral dominance for language functions from the start, as suggested by Botez and Crighel.[16] We believe that the second hypothesis best explains the clinical features.

Analysis of the left-handed anomia in our patient suggests that the right parietal lobe had no functional connection with the area of representation of speech in the right hemisphere, but was exclusively dependent of the area of representation of speech in the left hemisphere for naming objects placed in the left hand. Finally, it is interesting to note that the cerebral blood flow studies demonstrated decreased perfusion of the posterior zone of the frontal and parietal lobes of the right hemisphere and of the temporo-occipital area of the left hemisphere. These areas are considered to be possible representations of language functions. According to Nielsen,[14] lesions of the posterior part of the middle frontal gyrus (Hexner's area) or lesions of the angular gyrus can bring about agraphia. This author considered these zones to be the area of memorization of the writing movements and the area of visualization of written language, respectively, and believed that coordination of these two areas is necessary for the execution of writing movements.

According to Hrbek,[20] representation of the writing muscles' motor control is situated in the posterior part of the middle frontal gyrus, and that of the act of writing itself (praxia) is in the parietal lobe: lesions of these zones could produce agraphia. In our case, neuroradiological investigations showed no lesion in these part of the hemispheres. Decreased blood flow may be considered as a sign of decreased activity, which could be an indirect sign of the disconnection.

The second series of neuropsychological tests performed in this study were administered by P. Bachkine, MD, Hôpital La Pitié-Salpêtrière, Paris, France.

Professional Opportunities

KANSAS — Board-certified, board-eligible neurologist to join child neurologist in rebuilding a three-person practice in the largest city in Kansas. Three large, well-equipped hospitals available for resident and undergraduate medical education. Located in clean, progressive community described as the franchise capital of the country. Competitive salary and benefits available. Send CV to: Richard C. Gilmartin, MD, 2620 East Central, Wichita, KS 67214.

MAUI ORTHOPEDIC and Sports Medicine seeks neurologist to establish independent practice. Contact: William Gfeller, 450 Hookahi Street, Wailuku, Maui, HI 96793. (808) 244-5541.

SOUTHEAST COAST — Pediatric Neurologist: Excellent quality of life available in Savannah-Hilton Head Area, site of the 1996 Olympic Games sailing events. Outstanding recreational opportunities, nation's largest urban Historic District, and superb symphony are among the attractions of living here. A well-trained, personable neurologist with special competence in child neurology is needed for a busy practice, currently consisting of two adult neurologists and one neurologist doing adult and child neurology, all with strong academic backgrounds. CT, EEG, EMG and physical therapy are available in-office with large hospital practice available in three hospitals, including a major regional teaching hospital, affiliated with the Medical College of Georgia. First year guarantee is $80,000 plus bonus, leading to full partnership after two years. Earnings potential, availability of strong multi-specialty support, and opportunities for teaching are extraordinary. If interested contact: Randy Wellman, Office Manager, Savannah Neurological Associates, PC, P.O. Box 23059, Savannah, GA 31403. (912) 354-8151.

ADULT NEUROLOGIST to associate with two separate, busy solo neurologists. Practices are referral based, with two separate offices and three voluntary hospitals. Successful candidate would be expected to develop a separate solo, but collaborative practice. Established physicians would expect to provide substantial support for beginning physician. Opportunity would provide for cross coverage and joint venturing of facilities. Successful candidate should have excellent clinical skills. The medical community has excellent neurophysiology, neuroradiology, and neurosurgery. Located in a medium size city with both excellent living conditions and an extremely solid economic base. Please contact: Jeffrey A. Ribner, MD, 503 Plaza Drive, Vestal, NY 13850. (607) 729-1521 or Robert R. Taylor, Jr., MD, 269 Riverside Drive, Johnson City, NY 13790. (607) 798-7143.

NEUROLOGIST BC/BE — Washington, DC metropolitan area sought by busy four person group. We seek a personable, energetic clinician with competence in EEG, EMG, EP. Other subspecialty expertise welcomed. Respond with CV to: Larry Einbinder, MD, 8200 Wisconsin Avenue, Bethesda, MD 20814.

CAROLINA — PIEDMONT: BC/BE adult neurologist to join two neurologists in busy clinical practice. All neurodiagnostics available. Salary leading to partnership. Position available immediately. Send CV to: Marilyn Miller, 145 Dillon Drive, Spartanburg, SC 29302.

MELBOURNE, FLORIDA — Outstanding opportunity for an adult neurologist who would like to join a group of nine neurologists. Our group includes child neurologist, neuromuscular specialists and neurorehabilitation specialists. We live in a beautiful, high tech, beachside community with great schools and affordable housing. Please send CV to: Search Committee, P.O. Box 693, Melbourne, FL 32902.

Professional Opportunities

CLINICAL NEUROLOGIST — The Division of Neurology at The Mary Imogene Bassett Hospital is seeking a fourth neurologist in the practice of pediatric and adult neurology. The candidate must be BE/BC and interested in teaching. The Bassett Hospital is a multi-specialty group practice which provides primary and tertiary care to a ten-county rural region of Upstate New York, and is a major teaching affiliate of Columbia University. Members of the Division of Neurology hold faculty appointments at Columbia and Darmouth medical schools. The area combines environmental, recreational, and cultural advantages with excellent schools. We offer a competitive salary, faculty appointment, and liberal fringe benefits. Please send CV and correspondence to: Mary Anne Whelan, MD, Division of Neurology, The Mary Imogene Bassett Hospital, One Atwell Road, Cooperstown, NY 13326. (607) 547-3240.

METROPOLITAN WASHINGTON, DC AREA

Rapidly expanding neurology practice, with multiple locations, is seeking a BE/BC neurologist to join our dynamic team. Our offices are conveniently located, providing easy access to the areas finest hospitals as well as the nation's capital. We offer a competitive salary, excellent benefits and the opportunity for partnership. For more information please call or write:

William C. Nantz
10721 Main Street, Suite 2500
Fairfax, VA 22030 • (703) 352-5861

NEUROLOGIST — Beautiful Durango, Colorado is recruiting a BC/BE neurologist: Mercy Medical Center is an extremely progressive and active 100-bed facility and is doing well financially and growing — primarily due to an excellent staff of 90 physicians and a decent economy. Durango is located in southwestern Colorado, with an abundance of outdoor recreation (skiing, fishing, hunting, bicycling) excellent restaurants, an excellent local 4-year college, great weather and excellent schools! For more informaion about this excellent practice opportunity, mail CV or call: Bob Conrad, Vice President, Mercy Medical Center, 375 East Park Avenue, Durango, CO 81301. (303) 247-3804.

INDIANAPOLIS METROPOLITAN AREA: Young and aggressive Indianapolis neurological group seeks board-eligible or -certified associate. Broad spectrum of clinical experience is important. Experience in EEG, evoked potentials and EMG is necessary. Sub-specialty training is desirable, but not necessary. Indianapolis is a desirable, growing, clean and safe community. Excellent salary plus bonus and beneifts leading to partnership opportunity. Send CV to: Midwest Neurological Insitute, 998 East Main Street #202, Danville, IN 46122.

CHICAGO SUBURBAN solo practitioner with a busy practice seeking a full-time BC/BE clinical neurologist. EMG skills required. Immediate opening. Wonderful opportunity to expand with possible early partnership. Reply with CV to: Yvonne Jurcik, MD, 125 East Lake Cook Road, Buffalo Grove, IL 60089.

PLEASE NOTE—Address replies to box number ads as follows: Box number ______, c/o AON, P.O. Box 1510, Clearwater, FL 34617.

Professional Opportunities

EXCELLENT OPPORTUNITY for BC/BE neurologist to join 80-physician comprehensive, multispecialty group in San Francisco Bay Area. Large, varied referral base from Pediatrics, IM, FP, and Surgery. EMG/NCV, EEG, Evoked Response Testing, CT, MRI, Radiology support all available on site. Opportunity to interface with specialists of all types including neurosurgeons. Major university teaching affiliation encouraged and possible. Close proximity to 400-bed full service, modern hospital serving population of 300,000. Competitive guaranteed salary with bonus productivity plan for initial 18 months leading to partnership track. Extensive benefit package including housing incentives. Unique cultural, recreational and educational opportunities. Send CV to: Gary D. Zweig, MD, Recruitment Chairman, Sunnyvale Medical Clinic, P.O. Box 3496, Sunnyvale, CA 94088-3496.

OCHSNER NEUROLOGIST — The Ochsner Clinic of Baton Rouge seeks qualified neurologists to expand its department in our multi-specialty regional clinic. The practice offers an opportunity to practice in a setting which supports innovation and involvement in education and research. Competitive salary and excellent fringe benefits program. Send CV to: Ochsner Clinic of Baton Rouge, Physician Recruiting Support Services, 16777 Medical Center Drive, Baton Rouge, LA 70816; or call: (800) 488-2240.

NEUROLOGIST: Urban area in North Carolina. BC/BE, to join solo neurologist in a rapidly expanding, progressive and active practice. All neurodiagnostic modalities available. Excellent salary leading to partnership. Experience in EMG, EEG and EPs. Please reply with CV to: Box #822, c/o AON.

EXCELLENT OPPORTUNITY for BC/BE neurologist to practice in large eastern metropolitan area. Opening for July 1992 or earlier, for private practice with geographic full-time appointment at large teaching institution. Medical school appointment, teaching and research opportunities. Subspecialty in movement disorders, muscle diseases or neuro-oncology preferred but not required. Submit CV to: P.O. Box 5849, Pittsburgh, PA 15209-0849.

Neurologist

The Mason City Clinic
is a progressive
multi-specialty clinic in
the Heartland.

We are looking for a
neurologist to join our very
busy practice. Small-town
security within two
hours of Minneappolis
and Des Moines.

MRI, CT, sleep lab, EEG, EMG,
neurosurgery, cardiac surgery,
orthopedic surgery, cancer
center, GI lab, and ENT
capabilities.

Excellent salary
and benefits.

Submit CV to:

Ralph A. Wolf, Administrator
300 N. Eisenhower Avenue
Mason City, IA 50401
(515) 423-2435

ADULT NEUROLOGIST

Immediate private practice, solo and group opportunities available for board certified or board admissible neurologists in the following locations:

**** Middle Tennessee ****
****Florida Gulf Coast *North Carolina***
****North Central Indiana *South East Texas***

You will find excellent private practice opportunities in family oriented communities, competitive practice establishment packages which include salary/revenue guarantee, relocation and much more. Neurologists interested in these or other available positions are requested to send curriculum vitae in confidence to:

DENNIS BOTTOMLEY
Physician Placement Service of America
330 Franklin Rd.
Box 897
Brentwood, TN 37024
or call: 1-800-359-7421
FAX: 615-395-4764

BC/BE NEUROLOGIST — Exceptional opportunity to establish a practice in northwest Denver suburb. No investment required. Strong referral base. Opportunity to affiliate with two busy neurologists with office located adjacent to beautiful 400-bed hospital with state-of-the-art technology. Excellent opportunity for subspecialty trained with a strong interest in the clinical care of patients. Send CV to: Box #819, c/o AON.

NEUROLOGIST — The Cleveland VA Medical Center is recruiting for a part-time (5/8) position for a neurologist. The applicant must be board-certified or board-eligible in neurology, have expertise in both EMG and EEG and satisfy requirements for appointment in the Neurology Department at Case Western Reserve University. Responsibilities include attending neurology outpatient clinics in Youngstown, Canton, Brecksville, and Cleveland, Ohio, in addition to his/her responsibility for inpatient, consult services, reading EEGs and performing EMGs. Interested individuals should contact: Thomas R. Claflin at (216) 526-3030, Extension 7916. Or send a resume to his attention: Personnel Service 05(B), VAMC, 10000 Brecksville Road, Brecksville, OH 44141. The Cleveland VAMC is proud to be an equal employment opportunity employer.

SOUTHERN COLORADO — Exceptional practice and area. Opportunity to work with highly respected neurologist within a multi-specialty group. Practice to include: adult neurology, EEG, EMG, evoke potentials, CT and MRI. This vibrant community of 150,000 is located along the front range of the beautiful Rocky Mountains providing for a lifestyle second to none. Highly competitive first year income plus comprehensive benefits and relocation followed by partnership offering. For further details reply to: Wendy Perlman, 9360 Sunset Drive, Suite 250, Miami, FL 33173. Or call: (800) 368-2416, Extension 118.

CHARLOTTE, NORTH CAROLINA: High quality group of five neurologists, all of whom are subspecialized, seeks to add a well-trained specialist. Contact: Mike Kaufman, MD, 1900 Randolph Road, Suite 1010, Charlotte, NC 28207. Or call: (704) 334-7311.

Professional Opportunities

NEUROLOGIST WITH INTEREST in stroke, dementia, sleep or EEG to join existing neurologic group in southeastern Wisconsin. Two full-time neurologists and part-time pediatric neurologist and neuropsychologist. Rapidly expanding practice located one hour north of Chicago. Early partnership. Salary negotiable. Contact: Raymond J. Rybicki, MD, (414) 631-8550 or send CV to: 3803 Spring Street, Suite 201, Racine, WI 53405.

NEUROLOGIST — BC/BE to join main branch of thirty-five physician multi-specialty group. Excellent clinic and hospital facilities. Very competitive salary and benefit package. Excellent opportunity. Good hunting, fishing. Good schools, a beautiful place to raise a family. Call Executive Administrator collect (701) 857-0236, or write: Medical Arts Clinic, PC, P.O. Box 1489, Minot, ND 58702-1489.

SOUTHERN CALIFORNIA

Outstanding opportunity for motivated BC/BE neurologist with clinical and electrodiagnostic proficiency. Join a solo neurologist in an established and respected office and hospital-based practice. Balanced private/PPO/HMO profile. Excellent growth prospects.

New office with fully equipped eletrodiagnostic laboratory located in North Orange County. Area offers attractive living conditions, recreational opportunities and excellent public schools.

Generous guaranteed salary and benefit package with opportunity for early partnership.

Box 821, c/o AON

DURANGO, COLORADO: Need BC/BE neurologist to join neurosurgeon in southwest Colorado. Near 94 acute plus 11 skilled nursing bed hospital (Mercy Medical Center). 140,000 catchment area. No neurologist now based in Durango. Sole neurosurgeon presently in private practice, Medical Director Pain Rehabilitation Center, plus directs neurodiagnostic lab (EEG, EMG, NCV, evoked potentials, brain mapping, thermogram). Needs help! Great place to live — hiking, fishing, hunting, etc. Will split practice with right applicant. Spouse must be willing to live in small town rural area. Mail CV or call: Ben Crue, Jr, MD, FACS, 1130 Main Avenue, Durango, CO 81301. (303) 259-0779.

Positions Available

NEW ENGLAND SEACOAST COMMUNITY seeks second neurologist for community hospital practice. Excellent location with abundant outdoor recreation, good schools, major scientific institutions nearby. First year salary with early partnership option. Please contact: Michael Leahy, MD, 12 Bramblebush Park, Falmouth, MA 02540.

SOUTHERN CALIFORNIA — BC/BE clinician to join busy solo neurologist covering 320-bed hospital, complete neurodiagnostic laboratory and surrounding community. Contact: Thomas Di Julio, MD, 1703 Termino Avenue, Suite 208, Long Beach, CA 90274.

NEUROLOGIST: BC/BE. Must have skills in EEG, EMG and evoked potentials. To be associated with two neurologists in private practice, in a medical center location, with a expanding modern 181-bed hospital with complete modern equipment, and all specialties are represented. Situated in an attractive high desert area of the northwest with abundant recreational activities including the finest skiing, hiking, hunting, and fishing. Excellent schools available, both public and private. This is a very active practice in a drawing area of 175,000 and an excellent opportunity. Reply with curriculum vitae to: Box #823, c/o AON.

PLEASE NOTE—Address replies to box number ads as follows: Box number ________, c/o AON, P.O. Box 1510, Clearwater, FL 34617.

Fellowships

PEDIATRIC MOVEMENT Disorder Fellowships: Fellowship available in basic or clinical aspect of pediatric movement disorder for one or two years. Starting date is July 1, 1991. Candidates should have completed a neurology residency. This program stresses the neuropharmacology of movement disorders. Fellow will participate in federally sponsored clinical drug trials with a Research Nurse Practitioner in active outpatient and inpatient setting. For information contact: Dr. Michael R. Pranzatelli, Director, The National Pediatric Myoclonus Center, Neurology Department, Children's National Medical Center, 111 Michigan Avenue, NW, Washington, DC 20010. (202) 745-2120.

FELLOWSHIP IN CEREBROVASCULAR disease: Fellowships in cerebrovascular disease are available in the Department of Neurology at the University of Iowa. Comprehensive clinical training in diagnosis and management of patients with stroke is complemented by opportunities for clinical or basic research. Fellows are active participants in patient care and collaborate in several on-going local and multi-center clinical research studies. Candidates should be board-eligible or -certified in neurology and licensed to practice medicine in the United States. Please send inquiries to: Harold P. Adams, Jr, MD, Division of Cerebrovascular Diseases, Department of Neurology, University of Iowa, Iowa City, IA 52242; or call: (319) 356-4110. The University of Iowa is an affirmative action, equal opportunity employer. Women, minorities, and handicapped are encouraged to apply.

NATIONAL STROKE ASSOCIATION announces career-development fellowship awards ($30,000/year) for stroke research. Application due January 15, 1992 for July 1992 commencement. Contact: National Stroke Association, 300 East Hampden Avenue, #240, Englewood, CO 80110. (303) 762-9922.

PAIN FELLOWSHIP — The Pain Service in the Department of Neurology at Memorial Sloan-Kettering Cancer Center is seeking a board-eligible/board-certified neurologist for a pain fellowship. This is a one or two year position which offers comprehensive training in pain evaluation and treatment with a strong emphasis on cancer pain. Fellows will participate in clinical investigations of neuro-oncologic pain syndromes and the pharmacology of opioid analgesics. Laboratory research opportunities directed at the mechanisms of opiate action and the molecular pharmacology of opiate receptors are also available. Please contact: Kathleen M. Foley, MD, Department of Neurology, Memorial Sloan-Kettering Cancer Center, 1275 York Avenue, New York, NY 10021.

FELLOWSHIP IN EEG available immediately at combined VA hospital, Delaware/Thomas Jefferson University Program. Candidates with completed neurology residency. Contact: Leonard Katz, MD, VA Medical Center, Wilmington, DE 19805. (302) 994-2511.

MULTI-DISCIPLINARY FELLOWSHIP in pain medicine is being offered for July 1, 1992. Two-to-three year position is available with rotations in neurosurgery, neurology, oncology, anesthesia, and psychiatry. Clinical and basic science research projects will also be offered. Interested persons should submit inquiries and CV to: James Campbell, MD, Professor of Neurosurgery, c/o Kathleen Wiley, Pain Treatment Center, Johns Hopkins Hospital, Meyer 1-130, 600 North Wolfe Street, Baltimore, MD 21205.

Faculty Positions

ACADEMIC NEUROLOGIST sought with fellowship training in neuromuscular diseases and EMG. Opportunity to develop research program, teach neurology residents, and start a fellowship. State-of-the-art equipment and technician furnished. Nerve and muscle biopsy laboratory available in the department. Reply with CV to: Joseph B. Green, MD, Chairman, Department of Medical and Surgical Neurology, Texas Tech University Health Sciences Center, Lubbock, TX 79430. Texas Tech University is an equal opportunity employer.

Faculty Positions

ACADEMIC NEUROLOGIST sought with competence in sleep disorders to direct sleep center. Opportunity also in epilepsy, EEG, and evoked potentials, teach neurology residents and students. Reply with CV to: Joseph B. Green, MD, Chairman, Department of Medical and Surgical Neurology, Texas Tech University Health Sciences Center, Lubbock, TX 79430. Texas Tech University is an equal opportunity employer.

ACADEMIC NEUROLOGIST sought with training in cerebrovascular disease to develop program. Collaborate with neuropathology and radiology to develop research. Teach neurology residents. Reply with CV to: Joseph B. Green, MD, Chairman, Department of Medical and Surgical Neurology, Texas Tech University Health Sciences Center, Lubbock, TX 79430. Texas Tech University is an equal opportunity employer.

NEUROBIOLOGY/CLINICAL faculty positions — The Sanders-Brown Center on Aging at the University of Kentucky invites applications for two tenure-track faculty appointments at the Assistant Professor level from board-eligible/-certified neurologists or psychiatrists with basic neuroscience or clinical research interests in Alzheimer's disease. The successful candidates will have faculty appointments in the appropriate academic departments of the College of Medicine. The appointees will be expected to develop their own research programs, be willing to participate in multi-disciplinary Alzheimer's disease research and have some clinical responsibilities primarily related to dementing illnesses. Excellent start-up packages are available. The Sanders-Brown Center is one of the NIA-funded Alzheimer Disease Research Centers and has a separate 40,000 square foot building with excellent laboratory facilities. A letter of interest, a recent curriculum vitae and names of three references should be submitted to: William R. Markesbery, MD, Sanders-Brown Center on Aging, University of Kentucky, Lexington, KY 40536. (606) 233-6040. The University of Kentucky is an equal opportunity employer.

Associate Professor of Neurology/ Neuro-Oncology

The Department of Neurology at Temple University School of medicine seeks a Neuro-oncologist at the Associate Professor level to direct the clinical Neuro-oncology program at the Temple University Comprehensive Cancer Center. The program will provide comprehensive care for patients with primary and secondary CNS malignancy, indirect effects of systemic cancer and cancer pain. Facilities and support are available for the development of a clinical research program and collaborative opportunities are available in the area of molecular biology of brain tumors. Candidates should be board certified/board eligible in Neurology with additional fellowship training in Neuro-oncology. Applications should be forwarded to **Jeffrey I. Greenstein, M.D., Chair, Department of Neurology, Temple University School of Medicine, 3401 N. Broad Street, Philadelphia, PA 19140.** Temple University is an Equal Opportunity/Affirmative Action Employer.

Faculty Positions

ACADEMIC NEUROLOGIST — The Department of Neurology at Francis Scott Key Medical Center, a Johns Hopkins Medical Institution, seeks an academically-oriented adult BC/BE neurologist with expertise in EMG and NCV to run EMG Lab. Interest in neuromuscular assessment and research needed. Fellowship in EMG/NCV required with BC/BE in EMG (AAEM). The appointment will be full-time, at the Assistant Professor level, and will include responsibilities in research, clinical teaching, and patient care. Interested candidates should send a CV and three letters of reference to: Peter W. Kaplan, MD, Johns Hopkins School of Medicine, Francis Scott Key Medical Center, 4940 Eastern Avenue, Baltimore, MD 21224.

ACADEMIC NEUROLOGIST: A full-time academic position is available at the Assistant Professor level at Vanderbilt University Medical Center. Candidates should be board-certified/board-eligible in neurology and should have completed two years of full-time fellowship in epilepsy and clinical neurophysiology. The position includes teaching responsibilities and research. The preferred candidate will have experience in clinical epilepsy, long-term monitoring, electrocorticography, and experimental drug studies. Interested individuals should send CV to: Bassel Abou-Khalil, MD, Department of Neurology, Vanderbilt University Medical Center, 2100 Pierce Avenue, Room 336, Nashville, TN 37212.

Residencies

ADULT NEUROLOGY RESIDENCY PGY-IV position available at the University of Colorado School of Medicine for July, 1991. Contact: James P. Kelly, MA, MD, Director of Resident Selection, Department of Neurology, UCHSC B-183, 4200 East Ninth Avenue, Denver, CO 80262. (303) 270-8760.

NEUROLOGY RESIDENCY PROGRAM at the University of North Carolina. PGYII position available for entrance into Neurology Residency Program for 1992. Appointment will be made through the Neurology Residency Matching Program in 1992. Our program offers strong clinical training in general adult and child neurology as well as subspeciality exposure to epilepsy, sleep disorders, neuromuscular diseases and pain. For information contact: John A. Messenheimer, MD, School of Medicine, Department of Neurology, University of North Carolina, CB #7025, 751 Clinical Sciences Building, Chapel Hill, NC 27599-7025. (919) 966-3707.

THE UNIVERSITY OF Cincinnati Neurology Department is offering a second year neurology residency position (PGY III) beginning as soon as possible. For information contact: Joseph P. Broderick, MD, Residency Director, Department of Neurology, University of Cincinnati Medical Center, Cincinnati, OH 45267-0525. (513) 558-5431.

Dilantin® KAPSEALS® (Extended Phenytoin Sodium Capsules, USP)

Before prescribing, please see full prescribing information. A Brief Summary follows.

INDICATIONS AND USAGE: Dilantin is indicated for the control of generalized tonic-clonic (grand mal) and complex partial (psychomotor, temporal lobe) seizures and prevention and treatment of seizures occurring during or following neurosurgery.

Phenytoin serum level determinations may be necessary for optimal dosage adjustments (see Dosage and Administration and Clinical Pharmacology in the full prescribing information).

CONTRAINDICATIONS: Phenytoin is contraindicated in those patients who are hypersensitive to phenytoin or other hydantoins.

WARNINGS: Abrupt withdrawal of phenytoin in epileptic patients may precipitate status epilepticus. When, in the judgment of the clinician, the need for dosage reduction, discontinuation, or substitution of alternative antiepileptic medication arises, this should be done gradually. However, in the event of an allergic or hypersensitivity reaction, rapid substitution of alternative therapy may be necessary. In this case, alternative therapy should be an antiepileptic drug not belonging to the hydantoin chemical class.

There have been a number of reports suggesting a relationship between phenytoin and the development of lymphadenopathy (local or generalized) including benign lymph node hyperplasia, pseudolymphoma, lymphoma, and Hodgkin's Disease. Although a cause and effect relationship has not been established, the occurrence of lymphadenopathy indicates the need to differentiate such a condition from other types of lymph node pathology. Lymph node involvement may occur with or without symptoms and signs resembling serum sickness, eg, fever, rash and liver involvement.

In all cases of lymphadenopathy, follow-up observation for an extended period is indicated and every effort should be made to achieve seizure control using alternative antiepileptic drugs.

Acute alcoholic intake may increase phenytoin serum levels while chronic alcoholic use may decrease serum levels.

In view of isolated reports associating phenytoin with exacerbation of porphyria, caution should be exercised in using this medication in patients suffering from this disease.

Usage in Pregnancy: A number of reports suggests an association between the use of antiepileptic drugs by women with epilepsy and a higher incidence of birth defects in children born to these women. Data are more extensive with respect to phenytoin and phenobarbital, but these are also the most commonly prescribed antiepileptic drugs; less systematic or anecdotal reports suggest a possible similar association with the use of all known antiepileptic drugs.

Dilantin® Kapseals®
(extended phenytoin sodium capsules, USP)

The reports suggesting a higher incidence of birth defects in children of drug-treated epileptic women cannot be regarded as adequate to prove a definite cause and effect relationship. There are intrinsic methodological problems in obtaining adequate data on drug teratogenicity in humans; genetic factors or the epileptic condition itself may be more important than drug therapy in leading to birth defects. The great majority of mothers on antiepileptic medication deliver normal infants. It is important to note that antiepileptic drugs should not be discontinued in patients in whom the drug is administered to prevent major seizures, because of the strong possibility of precipitating status epilepticus with attendant hypoxia and threat to life. In individual cases where the severity and frequency of the seizure disorder are such that the removal of medication does not pose a serious threat to the patient, discontinuation of the drug may be considered prior to and during pregnancy, although it cannot be said with any confidence that even minor seizures do not pose some hazard to the developing embryo or fetus. The prescribing physician will wish to weigh these considerations in treating or counseling epileptic women of childbearing potential.

In addition to the reports of increased incidence of congenital malformation, such as cleft lip/palate and heart malformations, in children of women receiving phenytoin and other antiepileptic drugs, there have more recently been reports of a fetal hydantoin syndrome. This consists of prenatal growth deficiency, microcephaly and mental deficiency in children born to mothers who have received phenytoin, barbiturates, alcohol, or trimethadione. However, these features are all interrelated and are frequently associated with intrauterine growth retardation from other causes.

There have been isolated reports of malignancies, including neuroblastoma, in children whose mothers received phenytoin during pregnancy.

An increase in seizure frequency during pregnancy occurs in a high proportion of patients, because of altered phenytoin absorption or metabolism. Periodic measurement of serum phenytoin levels is particularly valuable in the management of a pregnant epileptic patient as a guide to an appropriate adjustment of dosage. However, postpartum restoration of the original dosage will probably be indicated.

Neonatal coagulation defects have been reported within the first 24 hours in babies born to epileptic mothers receiving phenobarbital and/or phenytoin. Vitamin K has been shown to prevent or correct this defect and has been recommended to be given to the mother before delivery and to the neonate after birth.

PRECAUTIONS: General: The liver is the chief site of biotransformation of phenytoin; patients with impaired liver function, elderly patients, or those who are gravely ill may show early signs of toxicity.

A small percentage of individuals who have been treated with phenytoin has been shown to metabolize the drug slowly. Slow metabolism may be due to limited enzyme availability and lack of induction; it appears to be genetically determined.

Phenytoin should be discontinued if a skin rash appears (see "Warnings" section regarding drug discontinuation). If the rash is exfoliative, purpuric, or bullous or if lupus erythematosus, Stevens-Johnson syndrome, or toxic epidermal necrolysis is suspected, use of this drug should not be resumed and alternative therapy should be considered. (See Adverse Reactions.) If the rash is of a milder type (measles-like or scarlatiniform), therapy may be resumed after the rash has completely disappeared. If the rash recurs upon reinstitution of therapy, further phenytoin medication is contraindicated.

Phenytoin and other hydantoins are contraindicated in patients who have experienced phenytoin hypersensitivity. Additionally, caution should be exercised if using structurally similar (eg, barbiturates, succinimides, oxazolidinediones and other related compounds) in these same patients.

Hyperglycemia, resulting from the drug's inhibitory effects on insulin release, has been reported. Phenytoin may also raise the serum glucose level in diabetic patients.

Osteomalacia has been associated with phenytoin therapy and is considered to be due to phenytoin's interference with Vitamin D metabolism.

Phenytoin is not indicated for seizures due to hypoglycemic or other metabolic causes. Appropriate diagnostic procedures should be performed as indicated.

Phenytoin is not effective for absence (petit mal) seizures. If tonic-clonic (grand mal) and absence (petit mal) seizures are present, combined drug therapy is needed.

Serum levels of phenytoin sustained above the optimal range may produce confusional states referred to as "delirium," "psychosis," or "encephalopathy," or rarely irreversible cerebell dysfunction. Accordingly, at the first sign of acute toxicity, plasma levels are recommended. Do reduction of phenytoin therapy is indicated if plasma levels are excessive; if symptoms persi termination is recommended. (See Warnings.)

Information for Patients: Patients taking phenytoin should be advised of the importance adhering strictly to the prescribed dosage regimen, and of informing the physician of any clinic condition in which it is not possible to take the drug orally as prescribed, eg, surgery, etc.

Patients should also be cautioned on the use of other drugs or alcoholic beverages without fi seeking the physician's advice.

Patients should be instructed to call their physician if skin rash develops.

The importance of good dental hygiene should be stressed in order to minimize t development of gingival hyperplasia and its complications.

Do not use capsules which are discolored.

Laboratory Tests: Phenytoin serum level determinations may be necessary to achieve optim dosage adjustments.

Drug Interactions: There are many drugs which may increase or decrease phenytoin levels which phenytoin may affect. Serum level determinations for phenytoin are especially helpf when possible drug interactions are suspected. The most commonly occurring drug interactio are listed below: 1. Drugs which may increase phenytoin serum levels include: acute alcoh intake, amiodarone, chloramphenicol, chlordiazepoxide, diazepam, dicumarol, disulfira estrogens, H_2-antagonists, halothane, isoniazid, methylphenidate, phenothiazine phenylbutazone, salicylates, succinimides, sulfonamides, tolbutamide, trazodone.

2. Drugs which may decrease phenytoin levels include: carbamazepine, chronic alcohol abus reserpine, and sucralfate. Moban® brand of molindone hydrochloride contains calcium io which interfere with the absorption of phenytoin. Ingestion times of phenytoin and antac preparations containing calcium should be staggered in patients with low serum phenytoin leve to prevent absorption problems.

3. Drugs which may either increase or decrease phenytoin serum levels include: phenobarbit sodium valproate, and valproic acid. Similarly, the effect of phenytoin on phenobarbital, valpro acid and sodium valproate serum levels is unpredictable.

4. Although not a true drug interaction, tricyclic antidepressants may precipitate seizures susceptible patients and phenytoin dosage may need to be adjusted.

5. Drugs whose efficacy is impaired by phenyto include: corticosteroids, coumarin anticoagulant digitoxin, doxycycline, estrogens, furosemide, or contraceptives, quinidine, rifampin, theophyllin vitamin D.

Drug/Laboratory Test Interactions: Phenytoin m cause decreased serum levels of protein-bound iodi (PBI). It may also produce lower than normal values f dexamethasone or metyrapone tests. Phenytoin m cause increased serum levels of glucose, alkaline pho phatase, and gamma glutamyl transpeptidase (GGT

Carcinogenesis: See "Warnings" section for inform tion on carcinogenesis.

Pregnancy: See Warnings.

Nursing Mothers: Infant breast-feeding is not recommended for women taking this drug becaus phenytoin appears to be secreted in low concentrations in human milk.

ADVERSE REACTIONS: Central Nervous System: The most common manifestations encountere with phenytoin therapy are referable to this system and are usually dose-related. These inclu nystagmus, ataxia, slurred speech, decreased coordination and mental confusion. Dizzines insomnia, transient nervousness, motor twitchings, and headaches have also been observed. The have also been rare reports of phenytoin induced dyskinesias, including chorea, dystonia, trem and asterixis, similar to those induced by phenothiazine and other neuroleptic drugs.

A predominantly sensory peripheral polyneuropathy has been observed in patients receivin long-term phenytoin therapy.

Gastrointestinal System: Nausea, vomiting, constipation, toxic hepatitis and liver damage.

Integumentary System: Dermatological manifestations sometimes accompanied by fever hav included scarlatiniform or morbilliform rashes. A morbilliform rash (measles-like) is the mo common; other types of dermatitis are seen more rarely. Other more serious forms which ma be fatal have included bullous, exfoliative or purpuric dermatitis, lupus erythematosus, Stevens Johnson syndrome, and toxic epidermal necrolysis (see Precautions).

Hemopoietic System: Hemopoietic complications, some fatal, have occasionally been reporte in association with administration of phenytoin. These have included thrombocytopenia, leuk penia, granulocytopenia, agranulocytosis, and pancytopenia with or without bone marrow sup pression. While macrocytosis and megaloblastic anemia have occurred, these conditions usuall respond to folic acid therapy. Lymphadenopathy including benign lymph node hyperplasia, pse dolymphoma, lymphoma, and Hodgkin's Disease have been reported (see Warnings).

Connective Tissue System: Coarsening of the facial features, enlargement of the lips, gingiv hyperplasia, hypertrichosis and Peyronie's Disease.

Cardiovascular: Periarteritis nodosa.

Immunologic: Hypersensitivity syndrome (which may include, but is not limited to, symptom such as arthralgias, eosinophilia, fever, liver dysfunction, lymphadenopathy or rash), systemi lupus erythematosus, immunoglobulin abnormalities.

OVERDOSAGE: The lethal dose in children is not known. The lethal dose in adults is estimate to be 2 to 5 grams. The initial symptoms are nystagmus, ataxia, and dysarthria. Other signs ar tremor, hyperreflexia, lethargy, slurred speech, nausea, vomiting. The patient may becom comatose and hypotensive. Death is due to respiratory and circulatory depression.

There are marked variations among individuals with respect to phenytoin plasma levels whe toxicity may occur. Nystagmus, on lateral gaze, usually appears at 20 mcg/mL, ataxia at 3 mcg/mL, dysarthria and lethargy appear when the plasma concentration is over 40 mcg/mL, bu as high a concentration as 50 mcg/mL has been reported without evidence of toxicity. As muc as 25 times the therapeutic dose has been taken to result in a serum concentration over 10 mcg/mL with complete recovery.

Treatment: Treatment is nonspecific since there is no known antidote.

The adequacy of the respiratory and circulatory systems should be carefully observed an appropriate supportive measures employed. Hemodialysis can be considered since phenytoi is not completely bound to plasma proteins. Total exchange transfusion has been used in th treatment of severe intoxication in children.

In acute overdosage the possibility of other CNS depressants, including alcohol, should b borne in mind.

Caution – Federal law prohibits dispensing without prescription. 0362G28

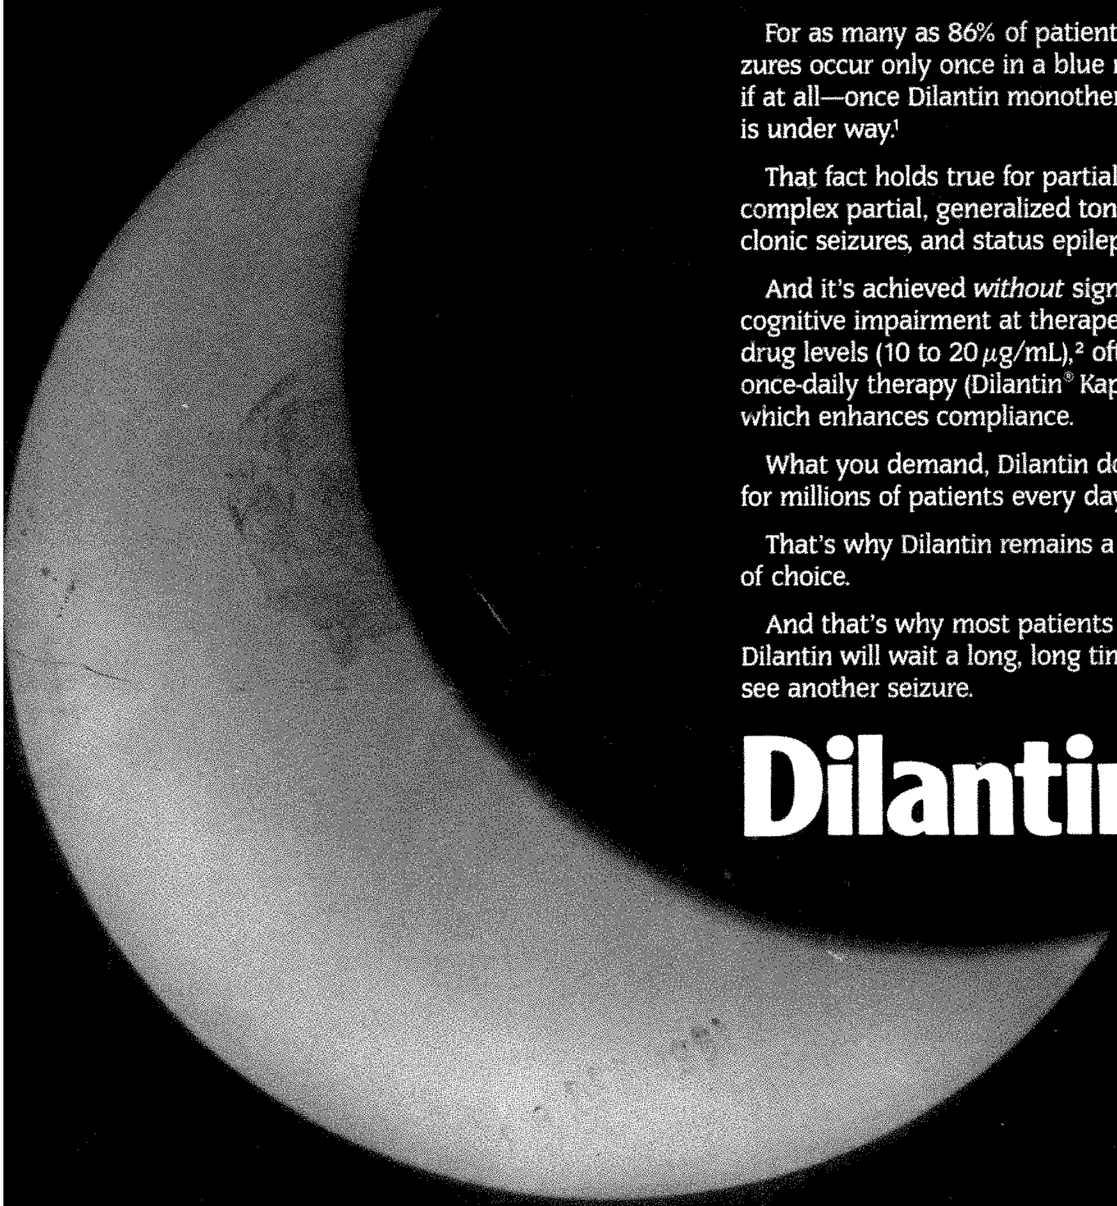
As rare as a seizure on Dilantin® (extended phenytoin sodium capsules, USP) 100 mg



For as many as 86% of patients, seizures occur only once in a blue moon—if at all—once Dilantin monotherapy is under way.[1]

That fact holds true for partial, complex partial, generalized tonic-clonic seizures, and status epilepticus.

And it's achieved *without* significant cognitive impairment at therapeutic drug levels (10 to 20 μg/mL),[2] often *with* once-daily therapy (Dilantin® Kapseals®), which enhances compliance.

What you demand, Dilantin does—for millions of patients every day.

That's why Dilantin remains a drug of choice.

And that's why most patients on Dilantin will wait a long, long time to see another seizure.

Dilantin®

"Once in a blue moon" describes the phenomenon in which the moon appears as a brilliant blue. Seen worldwide following the volcanic eruption of Krakatoa in 1883, the blue moon occurs only when atmospheric cloud droplets, each less than 5 μm in diameter, form in abundance—an exceedingly rare event.[3]

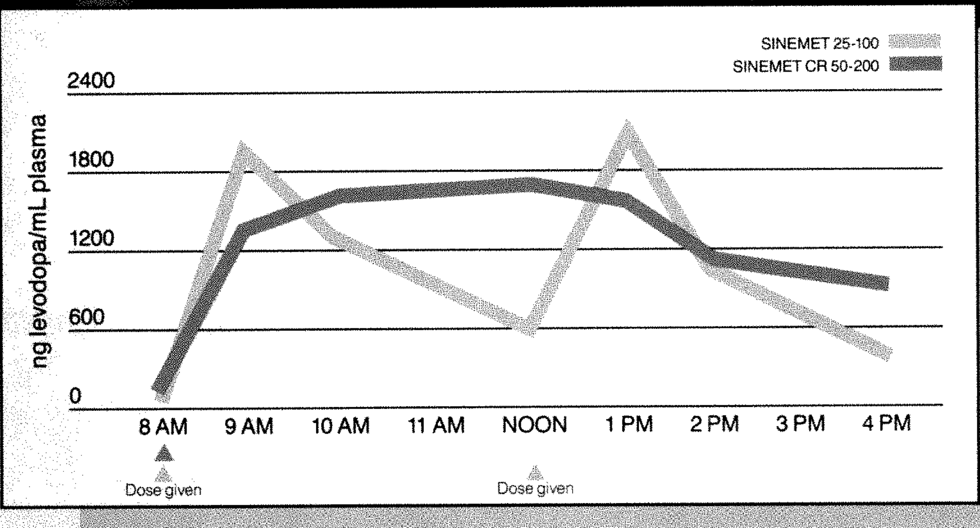
Smoother Plasma Levodopa Levels*



Less fluctuation of plasma levodopa levels with SINEMET CR vs SINEMET® (Carbidopa-Levodopa)[1]

In a clinical trial, 14 patients with mild to moderate Parkinson's disease had plasma levodopa levels measured over 8 hours after one dose of SINEMET CR, and were compared with levels over the same period after two doses of SINEMET 25-100.

Smoother plasma levodopa levels

The causes of motor fluctuations are not completely understood; *in some patients* they may be attenuated by treatment regimens that produce steady plasma levels of levodopa.

Reduced dosing frequency[2]

In a separate multicenter, double-blind trial of 202 patients with advanced Parkinson's disease, patients recorded a mean reduction of 33% in daily dosing frequency with SINEMET CR.[2]

---

*Patients should be advised that sometimes the onset of effect of the first morning dose of SINEMET CR may be delayed for up to 1 hour compared with the response usually obtained from the first morning dose of SINEMET. The physician should be notified if such delayed responses pose a problem in treatment.

Before prescribing SINEMET CR, please see Full Prescribing Information on the following pages.

® SINEMET is a registered trademark of Merck & Co., Inc., Rahway, NJ, USA
©1991 DuPont Pharmaceuticals Printed in USA CR-31092 8/91

SINEMET CR is indicated in the treatment of the symptoms of idiopath Parkinson's disease (paralysis agitans), postencephalitic parkinsonism and symptomatic parkinsonism which may follow injury to the nervous system by carbon monoxide intoxication and manganese intoxication.

1. Goetz CG, Tanner CM, Shannon KM, et al: Controlled-release carbidopa/levodor (CR4-Sinemet) in Parkinson's disease patients with and without motor fluctuatior *Neurology.* 1988;38:1143-1146.
2. Hutton JT, Morris JL, Bush DF, et al: Multicenter controlled study of Sinemet CR v Sinemet (25/100) in advanced Parkinson's disease. *Neurology.* 1989;39 (suppl 2): 67-72.

- Significantly greater benefits as rated by patients previously treated with SINEMET® (Carbidopa-Levodopa)‡[2]
- Although in clinical trials, patients with moderate to severe motor fluctuations who received SINEMET® CR (Carbidopa-Levodopa) Sustained-Release *did not experience quantitatively significant reductions* in "off" time when compared to SINEMET, global ratings of improvement as assessed by both patient and physician were better during therapy with SINEMET CR than with SINEMET.
- Significantly greater clinical improvement in patients with moderate to severe motor fluctuatio as rated by physicians**[2]
- In controlled clinical trials, patients predominantl with moderate to severe motor fluctuations while SINEMET were randomized to therapy with eithe SINEMET or SINEMET CR: *Adverse experience profile of SINEMET CR did not differ substantially from that of SINEMET.*

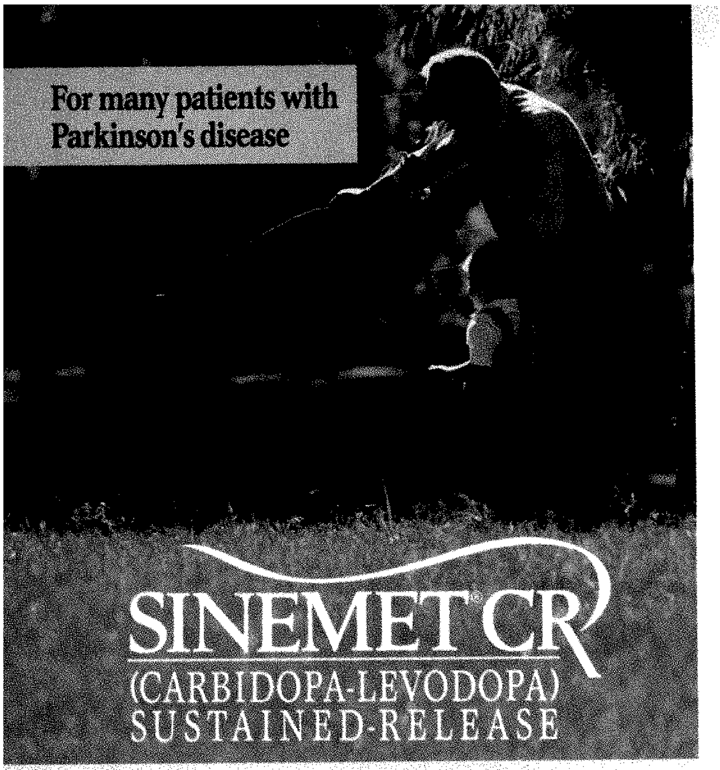
---

†In clinical trials of patients with moderate to severe motor fluctuations, global ratings of improvement as assessed by both patient and physician were better during therapy with SINEMET CR than with SINEMET.

‡Ratings based on patients' subjective assessment of global improvement in clinical fluctuations.

**Physician ratings based on significantly greater overall improvement in patient's clinical condition after eight weeks on SINEMET CR (compared to status at beginning of double-blind phase of same trials).[2]

When patients are receiving levodopa without a decarboxylase inhibitor, levodopa must be discontinued at least eight hours before SINEMET CR is started. It is necessary to individualize therapy. SINEMET CR should be substituted at a dosage that will provide approximately 25% of the previous levodopa dosage. Nonselective MAO inhibitors are contrain cated for use with SINEMET CR. These inhibitors must be discontinu at least two weeks prior to initiating therapy with SINEMET CR. SINEMET CR may be administered concomitantly with the manufacturer's recommended dose of an MAO inhibitor with selectivity for MAO type B, (e.g., selegiline HCl). SINEMET CR is contraindicated i patients with known hypersensitivity to any component of this drug a in patients with narrow-angle glaucoma. Because levodopa may activ a malignant melanoma, SINEMET CR should not be used in patients with suspicious, undiagnosed skin lesions or a history of melanoma.



Guidelines for Initial Conversion from SINEMET® to SINEMET CR

(Carbidopa-Levodopa)

- Dosage with SINEMET CR should be substituted at an amount that provides approximately 10% more levodopa per day. This may be increased to a dosage that provides up to 30% more levodopa per day depending on clinical response. (See DOSAGE AND ADMINISTRATION, *Titration.*)*
- Interval between doses of SINEMET CR should be 4-8 hours during the waking day.
- Doses and dosing intervals may be increased or decreased depending upon therapeutic response.

SINEMET Total daily dose levodopa (mg)	**SINEMET CR** Suggested dosage regimen†
300-400	1 tab b.i.d.
500-600	1½ tab b.i.d. or 1 tab t.i.d.
700-800	A total of 4 tabs in 3 or more divided doses (e.g., 1½ tab a.m., 1½ tab early p.m., and 1 tab later p.m.)
900-1000	A total of 5 tabs in 3 or more divided doses (e.g., 2 tabs a.m., 2 tabs early p.m., and 1 tab later p.m.)

The above is only provided as an example of conversion. Dosage must be individualized and will vary from patient to patient. This example chart reflects dosing of SINEMET CR to provide an increase of approximately 10% more levodopa.

*The bioavailability of levodopa from SINEMET CR relative to SINEMET is approximately 70%-75%.

†For dosing ranges not shown in the table see DOSAGE AND ADMINISTRATION, *Initial Dosage—Patients currently treated with conventional carbidopa-levodopa preparations* of enclosed Full Prescribing Information.

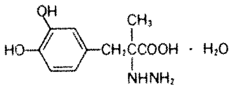
SINEMET® CR (CARBIDOPA-LEVODOPA)

SUSTAINED-RELEASE TABLETS

DESCRIPTION

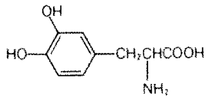
SINEMET* CR (Carbidopa-Levodopa) is a sustained-release combination of carbidopa and levodopa for t treatment of Parkinson's disease and syndrome.

Carbidopa, an inhibitor of aromatic amino acid decarboxylation, is a white, crystalline compound, slightly soluble in wa with a molecular weight of 244.3. It is designated chemically as (−)-L-α-hydrazino-α-methyl-β-(3,4-dihydroxybenzene) propar acid monohydrate. Its empirical formula is $C_{10}H_{14}N_2O_4 \bullet H_2O$ and its structural formula is:



Tablet content is expressed in terms of anhydrous carbidopa which has a molecular weight of 226.3.

Levodopa, an aromatic amino acid, is a white, crystalline compound slightly soluble in water, with a molecular wei of 197.2. It is designated chemically as (−)-L-α-amino-β-(3,4-dihydroxybenzene) propanoic acid. Its empirical formul $C_9H_{11}NO_4$ and its structural formula is



SINEMET CR is supplied as sustained-release tablets containing 50 mg of carbidopa and 200 mg of levodopa. Inac ingredients in SINEMET CR are: D & C Yellow 10, magnesium stearate, iron oxide, and other ingredients.

SINEMET CR is supplied as an oval, scored, biconvex, compressed tablet that is peach colored. The tablet is a polym based drug delivery system which controls the release of carbidopa and levodopa as it slowly erodes.

CLINICAL PHARMACOLOGY

Pharmacodynamics Current evidence indicates that symptoms of Parkinson's disease are related to depletion of d mine in the corpus striatum. Administration of dopamine is ineffective in the treatment of Parkinson's disease appare because it does not cross the blood-brain barrier. However, levodopa, the metabolic precursor of dopamine, does cross blood-brain barrier, and presumably is converted to dopamine in the brain. This is thought to be the mechanism whe levodopa relieves symptoms of Parkinson's disease.

When levodopa is administered orally it is rapidly decarboxylated to dopamine in extracerebral tissues so that only a s portion of a given dose is transported unchanged to the central nervous system. For this reason, large doses of levod are required for adequate therapeutic effect and these may often be attended by nausea and other adverse reactions, s of which are attributable to dopamine formed in extracerebral tissues.

Since levodopa competes with certain amino acids for transport across the gut wall, the absorption of levodopa ma impaired in some patients on a high protein diet.

Carbidopa inhibits decarboxylation of peripheral levodopa. It does not cross the blood-brain barrier and does not a the metabolism of levodopa within the central nervous system.

Since its decarboxylase inhibiting activity is limited to extracerebral tissues, administration of carbidopa with levo makes more levodopa available for transport to the brain.

Patients treated with levodopa therapy for Parkinson's disease may develop motor fluctuations characterized by en dose failure, peak dose dyskinesia, and akinesia. The advanced form of motor fluctuations ('on-off' phenomenon) is cha terized by unpredictable swings from mobility to immobility. Although the causes of the motor fluctuations are not c pletely understood, *in some patients* they may be attenuated by treatment regimens that produce steady plasma leve levodopa.

SINEMET CR contains 50 mg of carbidopa and 200 mg of levodopa in a sustained-release dosage form designed to rel these ingredients over a 4 to 6 hour period. With SINEMET CR there is less variation in plasma levodopa levels than SINEMET* (Carbidopa-Levodopa), the conventional formulation. *However, SINEMET CR (Carbidopa-Levodopa, Sustai Release) is less systemically bioavailable than SINEMET (Carbidopa-Levodopa) and may require increased daily doses to ac the same level of symptomatic relief as provided by SINEMET (Carbidopa-Levodopa).*

In clinical trials, patients with moderate to severe motor fluctuations *who received SINEMET CR did not experience q titatively significant reductions* in 'off' time when compared to SINEMET (Carbidopa-Levodopa). However, global ratin improvement as assessed by both patient and physician were better during therapy with SINEMET CR than with SINE (Carbidopa-Levodopa). In patients without motor fluctuations, SINEMET CR, under controlled conditions, provided the s therapeutic benefit with less frequent dosing when compared to SINEMET (Carbidopa-Levodopa).

Pyridoxine hydrochloride (vitamin B_6), in oral doses of 10 mg to 25 mg, may reverse the effects of levodopa by increa the rate of aromatic amino acid decarboxylation. Carbidopa inhibits this action of pyridoxine.

Pharmacokinetics Carbidopa reduces the amount of levodopa required to produce a given response by about 75 cent and, when administered with levodopa, increases both plasma levels and the plasma half-life of levodopa, and decre plasma and urinary dopamine and homovanillic acid.

Elimination half-life of levodopa in the presence of carbidopa is about 1.5 hours. Following SINEMET CR, the app half-life of levodopa may be prolonged because of continuous absorption.

In healthy elderly subjects (56-67 years old) the mean time to peak concentration of levodopa after a single do SINEMET CR 50-200 was about 2 hours as compared to 0.5 hours after standard SINEMET (Carbidopa-Levodopa). maximum concentration of levodopa after a single dose of SINEMET CR was about 35% of the standard SINEMET (Carbic Levodopa) (1151 vs 3256 ng/mL). The extent of availability of levodopa from SINEMET CR was about 70-75% relative to intrave levodopa or standard SINEMET (Carbidopa-Levodopa) in the elderly. The absolute bioavailability of levodopa SINEMET CR (relative to I.V.) in young subjects was shown to be only about 44%. The extent of availability and the peak centrations of levodopa were comparable in the elderly after a single dose and at steady state after t.i.d. administrati SINEMET CR 50-200. In elderly subjects, the average trough levels of levodopa at steady state after the CR tablet were a 2 fold higher than after the standard SINEMET (Carbidopa-Levodopa) (163 vs 74 ng/mL).

In these studies, using similar total daily doses of levodopa, plasma levodopa concentrations with SINEMET CR fl ated in a narrower range than with SINEMET (Carbidopa-Levodopa). Because the bioavailability of levodopa SINEMET CR relative to SINEMET (Carbidopa-Levodopa) is approximately 70-75% the daily dosage of levodopa nece to produce a given clinical response with the sustained-release formulation will usually be higher.

The extent of availability and peak concentrations of levodopa after a single dose of SINEMET CR 50-200, increas about 50% and 25%, respectively, when administered with food.

INDICATIONS AND USAGE

SINEMET CR is indicated in the treatment of the symptoms of idiopathic Parkinson's disease (paralysis agitans), po cephalitic parkinsonism, and symptomatic parkinsonism which may follow injury to the nervous system by carbon m ide intoxication and manganese intoxication.

CONTRAINDICATIONS

Nonselective MAO inhibitors are contraindicated for use with SINEMET CR. These inhibitors must be discontinued at two weeks prior to initiating therapy with SINEMET CR. SINEMET CR may be administered concomitantly with the mar turer's recommended dose of an MAO inhibitor with selectivity for MAO type B (e.g., selegiline HCl).

SINEMET CR is contraindicated in patients with known hypersensitivity to any component of this drug and in pa with narrow-angle glaucoma.

Because levodopa may activate a malignant melanoma, SINEMET CR should not be used in patients with suspic undiagnosed skin lesions or a history of melanoma.

WARNINGS

When patients are receiving levodopa without a decarboxylase inhibitor, levodopa must be discontinued at least eight before SINEMET CR is started. In order to reduce adverse reactions, it is necessary to individualize therapy. SINEM should be substituted at a dosage that will provide approximately 25 percent of the previous levodopa dosage (see DO AND ADMINISTRATION).

Carbidopa does not decrease adverse reactions due to central effects of levodopa. By permitting more levodopa to the brain, particularly when nausea and vomiting is not a dose-limiting factor, certain adverse CNS effects, e.g., dyskin will occur at lower dosages and sooner during therapy with SINEMET CR (Carbidopa-Levodopa, Sustained-Release with levodopa alone.

As with levodopa, SINEMET CR may cause involuntary movements and mental disturbances. These reactions are th to be due to increased brain dopamine following administration of levodopa. All patients should be observed caref the development of depression with concomitant suicidal tendencies. Patients with past or current psychoses sho treated with caution. The occurrence of dyskinesias may require dosage reduction.

Patients receiving SINEMET CR may develop increased dyskinesia compared to SINEMET (Carbidopa-Levodop

SINEMET CR should be administered cautiously to patients with severe cardiovascular or pulmonary disease, bro asthma, renal, hepatic or endocrine disease.

As with levodopa, care should be exercised in administering SINEMET CR to patients with a history of myocardial infarction who have residual atrial, nodal, or ventricular arrhythmias. In such patients, cardiac function should be monitored with particular care during the period of initial dosage adjustment, in a facility with provisions for intensive cardiac care.

As with levodopa, treatment with SINEMET CR may increase the possibility of upper gastrointestinal hemorrhage in patients with a history of peptic ulcer.

A symptom complex resembling the neuroleptic malignant syndrome including muscular rigidity, elevated body temperature, mental changes, and increased serum creatine phosphokinase has been reported when antiparkinsonian agents were withdrawn abruptly. Therefore, patients should be observed carefully when the dosage of SINEMET CR is reduced abruptly or discontinued, especially if the patient is receiving neuroleptics.

PRECAUTIONS

General As with levodopa, periodic evaluations of hepatic, hematopoietic, cardiovascular, and renal function are recommended during extended therapy.

Patients with chronic wide angle glaucoma may be treated cautiously with SINEMET CR provided the intraocular, pressure is well controlled and the patient is monitored carefully for changes in intraocular pressure during therapy.

Information for Patients The patient should be informed that SINEMET CR is a sustained-release formulation of carbidopa-levodopa which releases these ingredients over a 4 to 6 hour period. It is important that SINEMET CR be taken at regular intervals according to the schedule outlined by the physician. The patient should be cautioned not to change the prescribed dosage regimen and not to add any additional antiparkinson medications, including other carbidopa-levodopa preparations, without first consulting the physician.

If abnormal involuntary movements appear or get worse during treatment with SINEMET CR, the physician should be notified, as dosage adjustment may be necessary.

Patients should be advised that sometimes the onset of effect of the first morning dose of SINEMET CR may be delayed for up to 1 hour compared with the response usually obtained from the first morning dose of SINEMET (Carbidopa-Levodopa). The physician should be notified if such delayed responses pose a problem in treatment.

Patients must be advised that the whole or half tablet should be swallowed without chewing or crushing.

NOTE: The suggested advice to patients being treated with SINEMET CR is intended to aid in the safe and effective use of this medication. It is not a disclosure of all possible adverse or intended effects.

Laboratory Tests Abnormalities in laboratory tests may include elevations of liver function tests such as alkaline phosphatase, SGOT (AST), SGPT (ALT), lactic dehydrogenase, and bilirubin. Abnormalities in blood urea nitrogen and positive Coombs test have also been reported. Commonly, levels of blood urea nitrogen, creatinine, and uric acid are lower during administration of carbidopa-levodopa preparations than with levodopa.

Carbidopa-levodopa preparations may cause a false-positive reaction for urinary ketone bodies when a test tape is used for determination of ketonuria. This reaction will not be altered by boiling the urine specimen. False-negative tests may result with the use of glucose-oxidase methods of testing for glucosuria.

Drug Interactions *Caution should be exercised when the following drugs are administered concomitantly with SINEMET CR (Carbidopa-Levodopa, Sustained-Release).*

Symptomatic postural hypotension has occurred when carbidopa-levodopa preparations were added to the treatment of patients receiving some antihypertensive drugs. Therefore, when therapy with SINEMET CR is started, dosage adjustment of the antihypertensive drug may be required. For patients receiving monoamine oxidase inhibitors, see CONTRAINDICATIONS.

There have been rare reports of adverse reactions, including hypertension and dyskinesia, resulting from the concomitant use of tricyclic antidepressants and carbidopa-levodopa preparations.

Phenothiazines and butyrophenones may reduce the therapeutic effects of levodopa. In addition, the beneficial effects of levodopa in Parkinson's disease have been reported to be reversed by phenytoin and papaverine. Patients taking these drugs with SINEMET CR should be carefully observed for loss of therapeutic response.

Carcinogenesis, Mutagenesis, Impairment of Fertility In a two-year bioassay of SINEMET (Carbidopa-Levodopa), no evidence of carcinogenicity was found in rats receiving doses of approximately two times the maximum daily human dose of carbidopa and four times the maximum daily human dose of levodopa (equivalent to 8 SINEMET CR tablets).

In reproduction studies with SINEMET (Carbidopa-Levodopa), no effects on fertility were found in rats receiving doses of approximately two times the maximum daily human dose of carbidopa and four times the maximum daily human dose of levodopa (equivalent to 8 SINEMET CR tablets).

Pregnancy Pregnancy Category C. No teratogenic effects were observed in a study in mice receiving up to 20 times the maximum recommended human dose of SINEMET (Carbidopa-Levodopa). There was a decrease in the number of live pups delivered by rats receiving approximately two times the maximum recommended human dose of carbidopa and approximately five times the maximum recommended human dose of levodopa during organogenesis. SINEMET (Carbidopa-Levodopa) caused both visceral and skeletal malformations in rabbits at all doses and ratios of carbidopa/levodopa tested, which ranged from 10 times/5 times the maximum recommended human dose of carbidopa/levodopa to 20 times/10 times the maximum recommended human dose of carbidopa/levodopa.

There are no adequate or well-controlled studies in pregnant women. Use of SINEMET CR in women of childbearing potential requires that the anticipated benefits of the drug be weighed against possible hazards to mother and child.

Nursing Mothers It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when SINEMET CR is administered to a nursing mother.

Pediatric Use Safety and effectiveness in infants and children have not been established, and use of the drug in patients below the age of 18 is not recommended.

ADVERSE REACTIONS

In controlled clinical trials, patients predominantly with moderate to severe motor fluctuations, while on SINEMET (Carbidopa-Levodopa) were randomized to therapy with either SINEMET (Carbidopa-Levodopa) or SINEMET CR. The adverse experience frequency profile of SINEMET CR did not differ substantially from that of SINEMET (Carbidopa-Levodopa), as shown in Table 1.

Table 1 Clinical Adverse Experiences Occurring in 1% or Greater of Patients

Adverse Experience	**SINEMET CR** n=491 %	**SINEMET** (Carbidopa-Levodopa) n=524 %	Adverse Experience	**SINEMET CR** n=491 %	**SINEMET** (Carbidopa-Levodopa) n=524 %
Dyskinesia	16.5	12.2	Back Pain	1.6	0.6
Nausea	5.5	5.7	Dry Mouth	1.4	1.1
Hallucinations	3.9	3.2	Anorexia	1.2	1.1
Confusion	3.7	2.3	Diarrhea	1.2	0.6
Dizziness	2.9	2.3	Insomnia	1.2	1.0
Depression	2.2	1.3	Orthostatic Hypotension	1.0	1.1
Urinary Tract Infection	2.2	2.3	Shoulder Pain	1.0	0.6
Headache	2.0	1.9	Chest Pain	1.0	0.8
Dream Abnormalities	1.8	0.8	Muscle Cramps	0.8	1.0
Dystonia	1.8	0.8	Paresthesia	0.8	1.1
Vomiting	1.8	1.9	Urinary Frequency	0.8	1.1
Upper Respiratory Infection	1.8	1.0	Dyspepsia	0.6	1.1
Dyspnea	1.6	0.4	Constipation	0.2	1.5
'On-Off' Phenomena	1.6	1.1			

Abnormal laboratory findings occurring at a frequency of 1% or greater in approximately 443 patients who received SINEMET CR and 475 who received SINEMET (Carbidopa-Levodopa) during controlled clinical trials included: decreased hemoglobin and hematocrit; elevated serum glucose; white blood cells, bacteria and blood in the urine.

The adverse experiences observed in patients in uncontrolled studies were similar to those seen in controlled clinical studies.

Other adverse experiences reported overall in clinical trials in 748 patients treated with SINEMET CR, listed by body system in order of decreasing frequency, include:

Nervous System/Psychiatric: Chorea, somnolence, falling, anxiety disorder, disorientation, decreased mental acuity, gait abnormalities, extrapyramidal disorder, agitation, nervousness, sleep disorders, memory impairment.

Body as a Whole: Asthenia, fatigue, abdominal pain, orthostatic effects.

Digestive: Gastrointestinal pain, dysphagia, heartburn.

Cardiovascular: Palpitation, essential hypertension, hypotension, myocardial infarction.

Special Senses: Blurred vision.

Metabolic: Weight loss.

Skin: Rash.

Respiratory: Cough, pharyngeal pain, common cold.

Urogenital: Urinary incontinence.

Musculoskeletal: Leg pain.

Laboratory Tests: Decreased white blood cell count and serum potassium; increased BUN, serum creatinine and serum LDH; protein and glucose in the urine.

Other adverse experiences have been reported with various cabidopa-levodopa formulations and may occur with SINEMET CR:

Nervous System/Psychiatric: Mental changes including paranoid ideation, psychotic episodes, depression with suicidal tendencies and dementia; convulsions (however, a causal relationship has not been established); bradykinetic episodes.

Gastrointestinal: Gastrointestinal bleeding, development of duodenal ulcer. 76194

Cardiovascular: Cardiac irregularities, phlebitis. 625

Hematologic: Hemolytic and nonhemolytic anemia, thrombocytopenia, leukopenia, agranulocytosis.

Laboratory Tests: Abnormalities in alkaline phosphatase, SGOT (AST), SGPT (ALT), lactic dehydrogenase, bilirubin, protei bound iodine, Coombs test.

Other adverse reactions that have been reported with levodopa are:

Nervous System: Numbness, increased hand tremor, muscle twitching, blepharospasm (which may be taken as an ear sign of excess dosage, consideration of dosage reduction may be made at this time), trismus, activation of latent Horner syndrome.

Psychiatric: Delusions, euphoria.

Gastrointestinal: Bitter taste, sialorrhea, bruxism, hiccups, flatulence, burning sensation of tongue.

Metabolic: Weight gain, edema.

Integumentary: Malignant melanoma (see also CONTRAINDICATIONS), flushing, increased sweating, dark sweat, loss of ha

Genitourinary: Urinary retention, urinary incontinence, dark urine, priapism.

Miscellaneous: Faintness, hoarseness, malaise, hot flashes, sense of stimulation, bizarre breathing patterns, neurolept malignant syndrome.

OVERDOSAGE

Management of acute overdosage with SINEMET CR is the same as with levodopa. Pyridoxine is not effective in reversi the actions of SINEMET CR.

General supportive measures should be employed, along with immediate gastric lavage. Intravenous fluids should administered judiciously and an adequate airway maintained. Electrocardiographic monitoring should be instituted a the patient carefully observed for the development of arrhythmias; if required, appropriate antiarrhythmic therapy shou be given. The possibility that the patient may have taken other drugs as well as SINEMET CR should be taken into consider tion. To date, no experience has been reported with dialysis; hence, its value in overdosage is not known.

Based on studies in which high doses of levodopa and/or carbidopa were administered, a significant proportion of ra and mice given single oral doses of levodopa of approximately 1500-2000 mg/kg are expected to die. A significant propo tion of infant rats of both sexes are expected to die at a dose of 800 mg/kg. A significant proportion of rats are expected die after treatment with similar doses of carbidopa. The addition of carbidopa in a 1:10 ratio with levodopa increases t dose at which a significant proportion of mice are expected to die to 3360 mg/kg.

DOSAGE AND ADMINISTRATION

SINEMET CR tablets contain carbidopa (50 mg) and levodopa (200 mg) in a 1:4 ratio. The daily dosage of SINEMET CR mu be determined by careful titration. Patients should be monitored closely during the dose adjustment period, particular with regard to appearance or worsening of involuntary movements, dyskinesias or nausea. SINEMET CR may be administere as whole or as half-tablets which should not be chewed or crushed.

Standard drugs for Parkinson's disease, other than levodopa without a decarboxylase inhibitor, may be used concom tantly while SINEMET CR is being administered, although their dosage may have to be adjusted.

Since carbidopa prevents the reversal of levodopa effects caused by pyridoxine, SINEMET CR can be given to patien receiving supplemental pyridoxine (vitamin B_6).

Initial Dosage *Patients currently treated with conventional carbidopa-levodopa preparations:* Dosage with SINEMET C should be substituted at an amount that provides approximately 10% more levodopa per day, although this may need be increased to a dosage that provides up to 30% more levodopa per day depending on clinical response (see DOSAG AND ADMINISTRATION, TITRATION). The interval between doses of SINEMET CR should be 4-8 hours during the waki day. (See CLINICAL PHARMACOLOGY, *Pharmacodynamics*).

A guideline for *initiation* of SINEMET CR is shown in Table II.

TABLE II Guidelines for Initial Conversion from SINEMET (Carbidopa-Levodopa) to SINEMET CR	**SINEMET (Carbidopa-Levodopa)** Total Daily Dose* Levodopa (mg)	**SINEMET CR** Suggested Dosage Regimen
	300-400	1 tab b.i.d.
	500-600	1½ tab b.i.d. or 1 tab t.i.d.
	700-800	A total of 4 tabs in 3 or more divided doses (e.g., 1½ tab a.m., 1½ tab early p.m., and 1 tab later p.m.)
	900-1000	A total of 5 tabs in 3 or more divided doses (e.g., 2 tabs a.m., 2 tabs early p.m., and 1 tab later p.m.)

*For dosing ranges not shown in the table see DOSAGE AND ADMINISTRATION, *Initial Dosage—Patients currently treated with conventional carbidopa-levodopa preparations.*

Patients currently treated with levodopa without a decarboxylase inhibitor: Levodopa must be discontinued at least eight hou before therapy with SINEMET CR is started. SINEMET CR should be substituted at a dosage that will provide approximate 25% of the previous levodopa dosage. In patients with mild to moderate disease, the initial dose is usually 1 tablet SINEMET CR b.i.d.

Patients not receiving levodopa: In patients with mild to moderate disease, the initial recommended dose is 1 tablet SINEMET CR b.i.d. Initial dosage should not be given at intervals of less than 6 hours.

Titration Following initiation of therapy, doses and dosing intervals may be increased or decreased depending upon the apeutic response. Most patients have been adequately treated with 2 to 8 tablets per day, administered as divided dos at intervals ranging from 4 to 8 hours during the waking day. Higher doses (12 or more tablets per day) and shorter interva (less than 4 hours) have been used, but are not usually recommended.

When doses of SINEMET CR are given at intervals of less than 4 hours, and/or if the divided doses are not equal, it recommended that the smaller doses be given at the end of the day.

An interval of at least 3 days between dosage adjustments is recommended.

Maintenance Because Parkinson's disease is progressive, periodic clinical evaluations are recommended; adjustme of the dosage regimen of SINEMET CR may be required.

Addition of Other Antiparkinson Medications Anticholinergic agents, dopamine agonists, and amantadine can given with SINEMET CR. Dosage adjustment of SINEMET CR may be necessary when these agents are added.

A dose of SINEMET (Carbidopa-Levodopa) 25-100 or 10-100 (one half or a whole tablet) can be added to the dosage re men of SINEMET CR in selected patients with advanced disease who need additional levodopa for a brief time during da time hours.

Interruption of Therapy Patients should be observed carefully if abrupt reduction or discontinuation of SINEMET CR required, especially if the patient is receiving neuroleptics. (See WARNINGS).

If general anesthesia is required, SINEMET CR may be continued as long as the patient is permitted to take oral medic tion. If therapy is interrupted temporarily, the usual dosage should be administered as soon as the patient is able to ta oral medication.

HOW SUPPLIED

SINEMET CR 50-200 (Carbidopa-Levodopa) SUSTAINED-RELEASE TABLETS containing 50 mg of carbidopa and 200 m of levodopa, are peach-colored, oval, scored, biconvex, compressed tablets, coded 521. They are supplied as follows:

NDC 0056-0521-68 bottles of 100

NDC 0056-0521-28 unit dose packages of 100.

Storage Avoid temperatures above 30°C (86°F). Store in a tightly closed container.

SUBSCRIPTION RATES—The subscription rates for the ARCHIVES OF NEUROLOGY are as follows: $74 for 1 year, $133 for 2 years in the United States and US possessions; other countries, 1 year, $89; two years, $163 for surface delivery. For expedited delivery to most countries, add $15 surcharge for 1 year, $30 for 2 years. (Rates for subscriptions for delivery to Japan or South Korea are available through exclusive agents—contact the publisher.) ***Special rates for residents and medical students in the United States and US possessions are available.*** Address inquiries to the American Medical Association, Publishing Operations Division, 515 N State St, Chicago, IL 60610. Phone: **(312) 670-SUBS** (670-7827).

The **ARCHIVES OF NEUROLOGY** (ISSN 0003-9942) is published monthly by the American Medical Association, 515 N State St, Chicago, IL 60610, and is an official publication of the Association. Second-class postage paid at Chicago and at additional mailing office.

CHANGE OF ADDRESS—POSTMASTER, send all address changes to ARCHIVES OF NEUROLOGY, Attention: Subscription Department, 515 N State St, Chicago, IL 60610. Notification of address change must be made at least 6 weeks in advance. Include both old and new addresses, a recent mailing label, and your new ZIP code.

Please address communications concerning accepted or published communications to AMA Specialty Journals, 515 N State St, Chicago, IL 60610.

Stop the daily threat of migraine...

"Violent Passages" is a time-lapse portrayal by Louise Woodard depicting her own migraine headache sequence as she sees it. Her work focuses on the pain surrounding her eye and the confusion she feels as a result of the migraine.

with a daily dose of prevention.

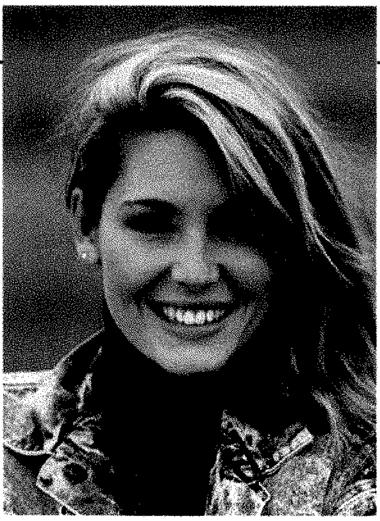
Migraine. It's agonizing, debilitating, unpredictable. And abortive therapies often provide inadequate relief or cause troublesome side effects for your patients.

Proven qd prophylaxis at recommended doses.

Only INDERAL® LA provides once-daily preventive therapy—to significantly reduce both frequency and severity of common migraine. **Start with 80 mg/day and titrate to an effective dose — usually 160 to 240 mg once daily.**

Well-tolerated, long-term efficacy.

For patients whose day-to-day lives are undermined by anticipation of migraine, INDERAL LA can offer an improved sense of control. Because the only thing worse than the pain of migraine is the threat of it.



ONCE-DAILY
INDERAL® LA
(PROPRANOLOL HCl) LONG ACTING CAPSULES 60, 80, 120, 160 mg

Another day without migraine.

Please see next page for brief summary of prescribing information.

INDERAL LA should not be used in the presence of congestive heart failure, sinus bradycardia, cardiogenic shock, heart block greater than first degree, and bronchial asthma.

© 1991, Wyeth-Ayerst Laboratories.

INDERAL® LA (propranolol HCl) Long Acting Capsules
BRIEF SUMMARY OF PRESCRIBING INFORMATION:
CONSULT THE PACKAGE LITERATURE FOR FULL PRESCRIBING INFORMATION.

CONTRAINDICATIONS. INDERAL is contraindicated in 1) cardiogenic shock; 2) sinus bradycardia and greater than first-degree block; 3) bronchial asthma; 4) congestive heart failure (see WARNINGS), unless the failure is secondary to a tachyarrhythmia treatable with INDERAL.

WARNINGS. CARDIAC FAILURE: Sympathetic stimulation may be a vital component supporting circulatory function in patients with congestive heart failure, and its inhibition by beta-blockade may precipitate more severe failure. Although beta blockers should be avoided in overt congestive heart failure, if necessary, they can be used with close follow-up in patients with a history of failure who are well compensated and are receiving digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle.

IN PATIENTS WITHOUT A HISTORY OF HEART FAILURE, continued use of beta blockers can, in some cases, lead to cardiac failure. Therefore, at the first sign or symptom of heart failure, the patient should be digitalized and/or treated with diuretics, and the response observed closely, or INDERAL should be discontinued (gradually, if possible).

IN PATIENTS WITH ANGINA PECTORIS, there have been reports of exacerbation of angina and, in some cases, myocardial infarction, following *abrupt* discontinuance of INDERAL therapy. Therefore, when discontinuance of INDERAL is planned, the dosage should be gradually reduced over at least a few weeks, and the patient should be cautioned against interruption or cessation of therapy without the physician's advice. If INDERAL therapy is interrupted and exacerbation of angina occurs, it usually is advisable to reinstitute INDERAL therapy and take other measures appropriate for the management of unstable angina pectoris. Since coronary artery disease may be unrecognized, it may be prudent to follow the above advice in patients considered at risk of having occult atherosclerotic heart disease who are given propranolol for other indications.

Nonallergic Bronchospasm (eg, chronic bronchitis, emphysema) – PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. INDERAL should be administered with caution since it may block bronchodilation produced by endogenous and exogenous catecholamine stimulation of beta receptors.

MAJOR SURGERY: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. It should be noted that the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.

INDERAL, like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects can be reversed by administration of such agents, eg, dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in starting and maintaining the heartbeat has also been reported with beta blockers.

DIABETES AND HYPOGLYCEMIA: Use beta blockers with caution in diabetic patients if a beta-blocking agent is required. Beta blockers may mask tachycardia occurring with hypoglycemia; other manifestations such as dizziness and sweating may not be significantly affected. Following insulin-induced hypoglycemia, propranolol may cause a delay in the recovery of blood glucose to normal levels.

THYROTOXICOSIS: Beta blockade may mask certain clinical signs of hyperthyroidism, thus abrupt withdrawal of propranolol may be followed by an exacerbation of symptoms of hyperthyroidism, including thyroid storm. Propranolol may change thyroid-function tests, increasing T_4 and reverse T_3, and decreasing T_3.

IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have been reported in which, after propranolol, tachycardia was replaced by severe bradycardia requiring a demand pacemaker. In one case this resulted after an initial dose of 5 mg propranolol.

PRECAUTIONS. GENERAL: Use with caution in patients with impaired hepatic or renal function. INDERAL is not indicated for the treatment of hypertensive emergencies.

Beta-adrenoreceptor blockade can cause reduction of intraocular pressure. Patients should be told that INDERAL may interfere with the glaucoma screening test. Withdrawal may lead to a return of increased intraocular pressure.

CLINICAL LABORATORY TESTS: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

DRUG INTERACTIONS: Patients receiving catecholamine-depleting drugs such as reserpine should be closely observed if INDERAL is administered. The added catecholamine-blocking action may produce an excessive reduction of resting sympathetic nervous activity resulting in hypotension, marked bradycardia, vertigo, syncopal attacks, or orthostatic hypotension.

Caution should be exercised when patients receiving a beta blocker are administered a calcium-channel-blocking drug, especially intravenous verapamil, as both agents may depress myocardial contractility or atrioventricular conduction. On rare occasions, the concomitant intravenous use of a beta blocker and verapamil has resulted in serious adverse reactions, especially in patients with severe cardiomyopathy, congestive heart failure or recent myocardial infarction.

Aluminum hydroxide gel greatly reduces intestinal absorption of propranolol.

Ethanol slows the rate of absorption of propranolol.

Phenytoin, phenobarbitone, and *rifampin* accelerate propranolol clearance.

Chlorpromazine, when used concomitantly with propranolol, results in increased plasma levels of both drugs.

Antipyrine and *lidocaine* have reduced clearance when used concomitantly with propranolol.

Thyroxine may result in a lower than expected T_3 concentration when used concomitantly with propranolol.

Cimetidine decreases the hepatic metabolism of propranolol, delaying elimination and increasing blood levels.

Theophylline clearance is reduced when used concomitantly with propranolol.

CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY: There was no evidence of significant drug-induced toxicity in rats or mice, employing doses up to 150 mg/kg/day over an 18-month period. There were no drug-related tumorigenic effects at any dosage levels. No impairment of fertility attributable to the drug was seen in animal reproductive studies.

PREGNANCY: Pregnancy Category C. INDERAL has been shown to be embryotoxic in animal studies at doses about 10 times greater than the maximum recommended human dose. There are no adequate and well-controlled studies in pregnant women. Use during pregnancy only if the potential benefit justifies the potential risk to the fetus.

NURSING MOTHERS: INDERAL is excreted in human milk. Exercise caution when INDERAL is administered to a nursing woman.

PEDIATRIC USE: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS. Most adverse effects have been mild and transient and have rarely required the withdrawal of therapy.

Cardiovascular: Bradycardia; congestive heart failure; intensification of AV block; hypotension; paresthesia of hands; thrombocytopenic purpura; arterial insufficiency, usually of the Raynaud type.

Central Nervous System: Light-headedness; mental depression manifested by insomnia, lassitude, weakness, fatigue; reversible mental depression progressing to catatonia; visual disturbances; hallucinations; vivid dreams; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics. For immediate formulations, fatigue, lethargy, and vivid dreams appear dose related.

Gastrointestinal: Nausea, vomiting, epigastric distress, abdominal cramping, diarrhea, constipation, mesenteric arterial thrombosis, ischemic colitis.

Allergic: Pharyngitis and agranulocytosis, erythematous rash, fever combined with aching and sore throat, laryngospasm, and respiratory distress.

Respiratory: Bronchospasm.

Hematologic: Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Auto-Immune: In extremely rare instances, systemic lupus erythematosus has been reported.

Miscellaneous: Alopecia, LE-like reactions, psoriasiform rashes, dry eyes, male impotence, and Peyronie's disease have been reported rarely. The oculomucocutaneous reactions associated with practolol have not been reported with propranolol.

DOSAGE AND ADMINISTRATION: INDERAL LA provides propranolol hydrochloride in a sustained-release capsule for administration once daily. If patients are switched from INDERAL Tablets to INDERAL LA Capsules, care should be taken to assure that the desired therapeutic effect is maintained. INDERAL LA should not be considered a simple mg-for-mg substitute for INDERAL. INDERAL LA has different kinetics and produces lower blood levels. Retitration may be necessary, especially to maintain effectiveness at the end of the 24-hour dosing interval.

For management of hypertension, angina pectoris, migraine, and hypertrophic subaortic stenosis the dosage must be individualized. Usual initial dose is 80 mg once daily.

If treatment is to be discontinued, reduce dosage gradually over a period of a few weeks (see WARNINGS).

PEDIATRIC DOSAGE – At this time the data on the use of the drug in this age group are too limited to permit adequate directions for use.

OVERDOSAGE. INDERAL is not significantly dialyzable. If ingestion is, or may have been, recent, evacuate gastric contents, taking care to prevent pulmonary aspiration.

BRADYCARDIA: Administer atropine (0.25 to 1.0 mg); if no response to vagal blockade, administer isoproterenol cautiously. CARDIAC FAILURE: digitalization and diuretics. HYPOTENSION: vasopressors, eg, levarterenol or epinephrine (there is evidence that epinephrine is the drug of choice). BRONCHOSPASM: administer isoproterenol and aminophylline.

The appearance of these capsules is a registered trademark of Ayerst Laboratories.

RE-INTRODUCE THE OLDEST ADVANCE IN MEDICINES.

It's called talking. If your older patients don't ask you about the prescriptions they've been given, make it a point to tell them what they need to know. Make sure they know the medicine's name, how and when to take it, precautions, and possible side effects. Encourage them to write down the information and ask you questions about things they don't understand.

You'll also want to take a complete medications history including both prescription *and* non-prescription medicines. The history can alert you to the potential for drug interactions and help you simplify their regimen.

Re-introduce the oldest advance in medicines. Make talking a crucial part of your practice. Because good, clear communication about medicines isn't a thing of the past. It's the way to a healthier future.

Before they take it,
talk about it.

EEG AND EVOKED POTENTIALS:
INTRAOPERATIVE AND ICU MONITORING

January 3 - 5, 1992
The Buena Vista Palace
Lake Buena Vista, Florida
In Walt Disney World Village

Course Directors: Betty Grundy, M.D., Michael Mahla, M.D., and William Friedman, M.D.

FACULTY: Geraldine Chadwick, M.A. C. Michael Harper, M.D.
Robin Gilmore, M.D. Rhonda Richards, B.A.
Salvatore Goodwin, M.D. Frank Sharbrough, M.D.
Kathryn Toney, B.S.

Learn all YOU need to know about EEG and Evoked Potential Monitoring

A distinguished faculty will present indications, methods, and interpretation techniques for EEG and evoked potential monitoring. Participants will be divided into small groups for a more personal, hands-on approach using a wide variety of EEG and evoked potential systems.

Course tuition is $450 ($500 after Nov. 30, 1991). Cancellation of registration by written notification only prior to Dec. 1, 1991. There is a $50 cancellation fee. This program has been approved for 19 hours of Category I credit toward the Physicians Recognition Award of the American Medical Association.

From refill to refill... which carbamazepine will your patient get next?

TEGRETOL is indicated for children 6 years and older and adults.

Because of the potential for serious hematologic adverse reactions, it is important that you become thoroughly familiar with the full Prescribing Information for TEGRETOL on the following page, especially the boxed warning.

BASEL

© 1991, CIBA-GEIGY Corporation.

Prevent substitution when you prescribe Tegretol

Sign each prescription on the line that prevents substitution, or add the phrase required in your state to prevent substitution:

☐ Dispense As Written
☐ No Substitution
☐ Do Not Substitute
☐ Brand Necessary
☐ No Drug Product Selection
☐ May Not Substitute
☐ Medically Necessary

For your Medicaid patients...

To prevent substitution of TEGRETOL for your Medicaid patients, be sure to add the phrase "Brand Medically Necessary" on each prescription.

Tegretol
carbamazepine USP

200 mg scored tablet
100 mg chewable tab

...because there's no substitute for experience.

Tegretol®

carbamazepine USP

Chewable Tablets of 100 mg—red-speckled, pink Tablets of 200 mg—pink

WARNING

APLASTIC ANEMIA AND AGRANULOCYTOSIS HAVE BEEN REPORTED IN ASSOCIATION WITH THE USE OF TEGRETOL. DATA FROM A POPULATION-BASED CASE CONTROL STUDY DEMONSTRATE THAT THE RISK OF DEVELOPING THESE REACTIONS IS 5-8 TIMES GREATER THAN IN THE GENERAL POPULATION. HOWEVER, THE OVERALL RISK OF THESE REACTIONS IN THE UNTREATED GENERAL POPULATION IS LOW, APPROXIMATELY SIX PATIENTS PER ONE MILLION POPULATION PER YEAR FOR AGRANULOCYTOSIS AND TWO PATIENTS PER ONE MILLION POPULATION PER YEAR FOR APLASTIC ANEMIA.

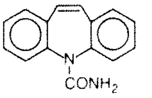
ALTHOUGH REPORTS OF TRANSIENT OR PERSISTENT DECREASED PLATELET OR WHITE BLOOD CELL COUNTS ARE NOT UNCOMMON IN ASSOCIATION WITH THE USE OF TEGRETOL, DATA ARE NOT AVAILABLE TO ESTIMATE ACCURATELY THEIR INCIDENCE OR OUTCOME. HOWEVER, THE VAST MAJORITY OF THE CASES OF LEUKOPENIA HAVE NOT PROGRESSED TO THE MORE SERIOUS CONDITIONS OF APLASTIC ANEMIA OR AGRANULOCYTOSIS.

BECAUSE OF THE VERY LOW INCIDENCE OF AGRANULOCYTOSIS AND APLASTIC ANEMIA, THE VAST MAJORITY OF MINOR HEMATOLOGIC CHANGES OBSERVED IN MONITORING OF PATIENTS ON TEGRETOL ARE UNLIKELY TO SIGNAL THE OCCURRENCE OF EITHER ABNORMALITY. NONETHELESS, COMPLETE PRETREATMENT HEMATOLOGICAL TESTING SHOULD BE OBTAINED AS A BASELINE. IF A PATIENT IN THE COURSE OF TREATMENT EXHIBITS LOW OR DECREASED WHITE BLOOD CELL OR PLATELET COUNTS, THE PATIENT SHOULD BE MONITORED CLOSELY. DISCONTINUATION OF THE DRUG SHOULD BE CONSIDERED IF ANY EVIDENCE OF SIGNIFICANT BONE MARROW DEPRESSION DEVELOPS.

Before prescribing Tegretol, the physician should be thoroughly familiar with the details of this prescribing information, particularly regarding use with other drugs, especially those which accentuate toxicity potential.

DESCRIPTION

Tegretol, carbamazepine USP, is an anticonvulsant and specific analgesic for trigeminal neuralgia, available as chewable tablets of 100 mg and tablets of 200 mg for oral administration. Its chemical name is 5H-dibenz[b,f]azepine-5-carboxamide, and its structural formula is



Carbamazepine USP is a white to off-white powder, practically insoluble in water and soluble in alcohol and in acetone. Its molecular weight is 236.27.

Inactive Ingredients. Colloidal silicon dioxide, FD&C Red No. 3 (chewable tablets only), FD&C Red No. 40 (200-mg tablets only), flavoring (chewable tablets only), gelatin, glycerin, magnesium stearate, sodium starch glycolate (chewable tablets only), starch, stearic acid, and sucrose (chewable tablets only).

CLINICAL PHARMACOLOGY

In controlled clinical trials, Tegretol has been shown to be effective in the treatment of psychomotor and grand mal seizures, as well as trigeminal neuralgia.

It has demonstrated anticonvulsant properties in rats and mice with electrically and chemically induced seizures. It appears to act by reducing polysynaptic responses and blocking the posttetanic potentiation. Tegretol greatly reduces or abolishes pain induced by stimulation of the infraorbital nerve in cats and rats. It depresses thalamic potential and bulbar and polysynaptic reflexes, including the linguomandibular reflex in cats. Tegretol is chemically unrelated to other anticonvulsants or other drugs used to control the pain of trigeminal neuralgia. The mechanism of action remains unknown.

Tegretol tablets are adequately absorbed after oral administration at a slower rate than a solution, thus avoiding undesirably high peak concentrations. Tegretol chewable tablets may produce higher peak levels than the same dose given as regular tablets. Tegretol in blood is 76% bound to plasma proteins. Plasma levels of Tegretol are variable and may range from 0.5-25 μg/ml, with no apparent relationship to the daily intake of the drug. Usual adult therapeutic levels are between 4 and 12 μg/ml. Following oral administration, serum levels peak at 4 to 5 hours. The CSF/serum ratio is 0.22, similar to the 22% unbound Tegretol in serum. Because Tegretol may induce its own metabolism, the half-life is also variable. Initial half-life values range from 25-65 hours, with 12-17 hours on repeated doses. Tegretol is metabolized in the liver. After oral administration of 14C-carbamazepine, 72% of the administered radioactivity was found in the urine and 28% in the feces. This urinary radioactivity was composed largely of hydroxylated and conjugated metabolites, with only 3% of unchanged Tegretol. Transplacental passage of Tegretol is rapid (30 to 60 minutes), and the drug is accumulated in fetal tissues, with higher levels found in liver and kidney than in brain and lungs.

INDICATIONS AND USAGE

Epilepsy: Tegretol is indicated for use as an anticonvulsant drug. Evidence supporting efficacy of Tegretol as an anticonvulsant was derived from active drug-controlled studies that enrolled patients with the following seizure types:

1. Partial seizures with complex symptomatology (psychomotor, temporal lobe). Patients with these seizures appear to show greater improvement than those with other types.
2. Generalized tonic-clonic seizures (grand mal).
3. Mixed seizure patterns which include the above, or other partial or generalized seizures.

Absence seizures (petit mal) do not appear to be controlled by Tegretol (see PRECAUTIONS, General).

Trigeminal Neuralgia: Tegretol is indicated in the treatment of the pain associated with true trigeminal neuralgia.

Beneficial results have also been reported in glossopharyngeal neuralgia.

This drug is not a simple analgesic and should not be used for the relief of trivial aches or pains.

CONTRAINDICATIONS

Tegretol should not be used in patients with a history of previous bone marrow depression, hypersensitivity to the drug, or known sensitivity to any of the tricyclic compounds, such as amitriptyline, desipramine, imipramine, protriptyline, nortriptyline, etc. Likewise, on theoretical grounds its use with monoamine oxidase inhibitors is not recommended. Before administration of Tegretol, MAO inhibitors should be discontinued for a minimum of fourteen days, or longer if the clinical situation permits.

WARNINGS

Patients with a history of adverse hematologic reaction to any drug may be particularly at risk.

Severe dermatologic reactions including toxic epidermal necrolysis (Lyell's syndrome) and Stevens-Johnson syndrome, have been reported with Tegretol. These reactions have been extremely rare. However, a few fatalities have been reported.

Tegretol has shown mild anticholinergic activity; therefore, patients with increased intraocular pressure should be closely observed during therapy.

Because of the relationship of the drug to other tricyclic compounds, the possibility of activation of a latent psychosis and, in elderly patients, of confusion or agitation should be borne in mind.

PRECAUTIONS

General: Before initiating therapy, a detailed history and physical examination should be made.

Tegretol should be used with caution in patients with a mixed seizure disorder that includes atypical absence seizures, since in these patients Tegretol has been associated with increased frequency of generalized convulsions (see INDICATIONS AND USAGE).

Therapy should be prescribed only after critical benefit-to-risk appraisal in patients with a history of cardiac, hepatic or renal damage, adverse hematologic reaction to other drugs, or interrupted courses of therapy with Tegretol.

Information for Patients: Patients should be made aware of the early toxic signs and symptoms of a potential hematologic problem, such as fever, sore throat, ulcers in the mouth, easy bruising, petechial or purpuric hemorrhage, and should be advised to report to the physician immediately if any such signs or symptoms appear.

Since dizziness and drowsiness may occur, patients should be cautioned about the hazards of operating machinery or automobiles or engaging in other potentially dangerous tasks.

Laboratory Tests: Complete pretreatment blood counts, including platelets and possibly reticulocytes and serum iron, should be obtained as a baseline. If a patient in the course of treatment exhibits low or decreased white blood cell or platelet counts, the patient should be monitored closely. Discontinuation of the drug should be considered if any evidence of significant bone marrow depression develops.

Baseline and periodic evaluations of liver function, particularly in patients with a history of liver disease, must be performed during treatment with this drug since liver damage may occur. The drug should be discontinued immediately in cases of aggravated liver dysfunction or active liver disease.

Baseline and periodic eye examinations, including slit-lamp, funduscopy and tonometry, are recommended since many phenothiazines and related drugs have been shown to cause eye changes.

Baseline and periodic complete urinalysis and BUN determinations are recommended for patients treated with this agent because of observed renal dysfunction.

Monitoring of blood levels (see CLINICAL PHARMACOLOGY) has increased the efficacy and safety of anticonvulsants. This monitoring may be particularly useful in cases of dramatic increase in seizure frequency and for verification of compliance. In addition, measurement of drug serum levels may aid in determining the cause of toxicity when more than one medication is being used.

Thyroid function tests have been reported to show decreased values with Tegretol administered alone.

Hyponatremia has been reported in association with Tegretol use, either alone or in combination with other drugs.

Drug Interactions: The simultaneous administration of phenobarbital, phenytoin, or primidone, or a combination of two, produces a marked lowering of serum levels of Tegretol. The effect of valproic acid on Tegretol blood levels is not clearly established, although an increase in the ratio of active 10, 11-epoxide metabolite to parent compound is a consistent finding.

The half-lives of phenytoin, warfarin, doxycycline, and theophylline were significantly shortened when administered concurrently with Tegretol. Haloperidol and valproic acid serum levels may be reduced when these drugs are administered with Tegretol. The doses of these drugs may therefore have to be increased when Tegretol is added to the therapeutic regimen.

Concomitant administration of Tegretol with erythromycin, cimetidine, propoxyphene, isoniazid, fluoxetine or calcium channel blockers has been reported to result in elevated plasma levels of carbamazepine resulting in toxicity in some cases. Also, concomitant administration of carbamazepine and lithium may increase the risk of neurotoxic side effects.

Alterations of thyroid function have been reported in combination therapy with other anticonvulsant medications.

Breakthrough bleeding has been reported among patients receiving concomitant oral contraceptives and their reliability may be adversely affected.

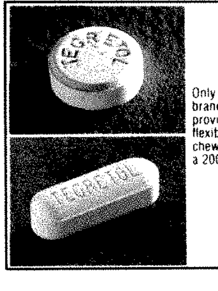
Carcinogenesis, Mutagenesis, Impairment of Fertility: Carbamazepine, when administered to Sprague-Dawley rats for two years in the diet at doses of 25, 75, and 250 mg/kg/day, resulted in a dose-related increase in the incidence of hepatocellular tumors in females and of benign interstitial cell adenomas in the testes of males.

Carbamazepine must, therefore, be considered to be carcinogenic in Sprague-Dawley rats. Bacterial and mammalian mutagenicity studies using carbamazepine produced negative results. The significance of these findings relative to the use of carbamazepine in humans is, at present, unknown.

Pregnancy Category C: Tegretol has been shown to have adverse effects in reproduction studies in rats when given orally in dosages 10-25 times the maximum human daily dosage of 1200 mg. In rat teratology studies, 2 of 135 offspring showed kinked ribs at 250 mg/kg and 4 of 119 offspring at 650 mg/kg showed other anomalies (cleft palate, 1; talipes, 1; anophthalmos, 2). In reproduction studies in rats, nursing offspring demonstrated a lack of weight gain and an unkempt appearance at a maternal dosage level of 200 mg/kg.

There are no adequate and well-controlled studies in pregnant women. Epidemiological data suggest that there may be an association between the use of carbamazepine during pregnancy and congenital malformations, including spina bifida. Tegretol should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Retrospective case reviews suggest that, compared with monotherapy, there may be a higher prevalence of teratogenic effects associated with the use of anticonvulsants in combination therapy. Therefore, monotherapy is recommended for pregnant women.



Only TEGRETOL,
brand of carbamazepine,
provides the prescribing
flexibility of a 100-mg scored
chewable tablet, as well as
a 200-mg scored tablet

It is important to note that anticonvulsant drugs should not be discontinued in patients in whom the drug is administered to prevent major seizures because of the strong possibility of precipitating status epilepticus with attendant hypoxia and threat to life. In individual cases where the severity and frequency of the seizure disorder are such that removal of medication does not pose a serious threat to the patient, discontinuation of the drug may be considered prior to and during pregnancy, although it cannot be said with any confidence that even minor seizures do not pose some hazard to the developing embryo or fetus.

Labor and Delivery: The effect of Tegretol on human labor and delivery is unknown.

Nursing Mothers: During lactation, concentration of Tegretol in milk is approximately 60% of the maternal plasma concentration.

Because of the potential for serious adverse reactions in nursing infants from carbamazepine, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use: Safety and effectiveness in children below the age of 6 years have not been established.

ADVERSE REACTIONS

If adverse reactions are of such severity that the drug must be discontinued, the physician must be aware that abrupt discontinuation of any anticonvulsant drug in a responsive epileptic patient may lead to seizures or even status epilepticus with its life-threatening hazards.

The most severe adverse reactions have been observed in the hemopoietic system (see boxed WARNING), the skin and the cardiovascular system.

The most frequently observed adverse reactions, particularly during the initial phases of therapy, are dizziness, drowsiness, unsteadiness, nausea, and vomiting. To minimize the possibility of such reactions, therapy should be initiated at the low dosage recommended.

The following additional adverse reactions have been reported:

Hemopoietic System: Aplastic anemia, agranulocytosis, pancytopenia, bone marrow depression, thrombocytopenia, leukopenia, leukocytosis, eosinophilia, acute intermittent porphyria.

Skin. Pruritic and erythematous rashes, urticaria, toxic epidermal necrolysis (Lyell's syndrome) (see WARNINGS), Stevens-Johnson syndrome (see WARNINGS), photosensitivity reactions, alterations in skin pigmentation, exfoliative dermatitis, erythema multiforme and nodosum, purpura, aggravation of disseminated lupus erythematosus, alopecia, and diaphoresis. In certain cases, discontinuation of therapy may be necessary. Isolated cases of hirsutism have been reported, but a causal relationship is not clear.

Cardiovascular System: Congestive heart failure, edema, aggravation of hypertension, hypotension, syncope and collapse, aggravation of coronary artery disease, arrhythmias and AV block, primary thrombophlebitis, recurrence of thrombophlebitis, and adenopathy or lymphadenopathy.

Some of these cardiovascular complications have resulted in fatalities. Myocardial infarction has been associated with other tricyclic compounds.

Liver: Abnormalities in liver function tests, cholestatic and hepatocellular jaundice, hepatitis.

Respiratory System: Pulmonary hypersensitivity characterized by fever, dyspnea, pneumonitis or pneumonia.

Genitourinary System: Urinary frequency, acute urinary retention, oliguria with elevated blood pressure, azotemia, renal failure, and impotence. Albuminuria, glycosuria, elevated BUN and microscopic deposits in the urine have also been reported.

Testicular atrophy occurred in rats receiving Tegretol orally from 4 to 52 weeks at dosage levels of 50 to 400 mg/kg/day. Additionally, rats receiving Tegretol in the diet for two years at dosage levels of 25, 75, and 250 mg/kg/day had a dose-related incidence of testicular atrophy and aspermatogenesis. In dogs, it produced a brownish discoloration, presumably a metabolite, in the urinary bladder at dosage levels of 50 mg/kg and higher. Relevance of these findings to humans is unknown.

Nervous System: Dizziness, drowsiness, disturbances of coordination, confusion, headache, fatigue, blurred vision, visual hallucinations, transient diplopia, oculomotor disturbances, nystagmus, speech disturbances, abnormal involuntary movements, peripheral neuritis and paresthesias, depression with agitation, talkativeness, tinnitus, and hyperacusis.

There have been reports of associated paralysis and other symptoms of cerebral arterial insufficiency, but the exact relationship of these reactions to the drug has not been established.

Digestive System: Nausea, vomiting, gastric distress and abdominal pain, diarrhea, constipation, anorexia, and dryness of the mouth and pharynx, including glossitis and stomatitis.

Eyes. Scattered, punctate, cortical lens opacities, as well as conjunctivitis have been reported. Although a direct causal relationship has not been established, many phenothiazines and related drugs have been shown to cause eye changes.

Musculoskeletal System: Aching joints and muscles, and leg cramps.

Metabolism: Fever and chills. Inappropriate antidiuretic hormone (ADH) secretion syndrome has been reported. Cases of frank water intoxication, with decreased serum sodium (hyponatremia) and confusion, have been reported in association with Tegretol use (see PRECAUTIONS, Laboratory Tests).

Other: Isolated cases of a lupus erythematosus-like syndrome have been reported. There have been occasional reports of elevated levels of cholesterol, HDL cholesterol and triglycerides in patients taking anticonvulsants.

A case of aseptic meningitis, accompanied by myoclonus and peripheral eosinophilia has been reported in a patient taking carbamazepine in combination with other medications. The patient was successfully dechallenged, and the meningitis reappeared upon rechallenge with carbamazepine.

DRUG ABUSE AND DEPENDENCE

No evidence of abuse potential has been associated with Tegretol, nor is there evidence of psychological or physical dependence in humans.

OVERDOSAGE

Acute Toxicity

Lowest known lethal dose: adults, >60 g (39-year-old man). Highest known doses survived: adults, 30 g (31-year-old woman); children, 10 g (6-year-old boy); small children, 5 g (3-year-old girl).

Oral LD 50 in animals (mg/kg): mice, 1100-3750; rats, 3850-4025; rabbits, 1500-2680; guinea pigs, 920.

Signs and Symptoms

The first signs and symptoms appear after 1-3 hours. Neuromuscular disturbances are the most prominent. Cardiovascular disorders are generally milder, and severe cardiac complications occur only when very high doses (>60 g) have been ingested.

Respiration: Irregular breathing, respiratory depression.

Cardiovascular System: Tachycardia, hypotension or hypertension, shock, conduction disorders.

Nervous System and Muscles: Impairment of consciousness ranging in severity to deep coma. Convulsions, especially in small children. Motor restlessness, muscular twitching, tremor, athetoid movements, opisthotonos, ataxia, drowsiness, dizziness, mydriasis, nystagmus, adiadochokinesia, ballism, psychomotor disturbances, dysmetria. Initial hyperreflexia, followed by hyporeflexia.

Gastrointestinal Tract: Nausea, vomiting.

Kidneys and Bladder: Anuria or oliguria, urinary retention.

Laboratory Findings: Isolated instances of overdosage have included leukocytosis, reduced leukocyte count, glycosuria and acetonuria. EEG may show dysrhythmias.

Combined Poisoning: When alcohol, tricyclic antidepressants, barbiturates or hydantoins are taken at the same time, the signs and symptoms of acute poisoning with Tegretol may be aggravated or modified.

Treatment

The prognosis in cases of severe poisoning is critically dependent upon prompt elimination of the drug, which may be achieved by inducing vomiting, irrigating the stomach, and by taking appropriate steps to diminish absorption. If these measures cannot be implemented without risk on the spot, the patient should be transferred at once to a hospital, while ensuring that vital functions are safeguarded. There is no specific antidote.

Elimination of the Drug: Induction of vomiting.

Gastric lavage. Even when more than 4 hours have elapsed following ingestion of the drug, the stomach should be repeatedly irrigated, especially if the patient has also consumed alcohol.

Measures to Reduce Absorption: Activated charcoal, laxatives.

Measures to Accelerate Elimination: Forced diuresis.

Dialysis is indicated only in severe poisoning associated with renal failure. Replacement transfusion is indicated in severe poisoning in small children.

Respiratory Depression. Keep the airways free; resort, if necessary, to endotracheal intubation, artificial respiration, and administration of oxygen.

Hypotension, Shock: Keep the patient's legs raised and administer a plasma expander. If blood pressure fails to rise despite measures taken to increase plasma volume, use of vasoactive substances should be considered.

Convulsions: Diazepam or barbiturates.

Warning: Diazepam or barbiturates may aggravate respiratory depression (especially in children), hypotension, and coma. However, barbiturates should not be used if drugs that inhibit monoamine oxidase have also been taken by the patient either in overdosage or in recent therapy (within one week).

Surveillance: Respiration, cardiac function (ECG monitoring), blood pressure, body temperature, pupillary reflexes, and kidney and bladder function should be monitored for several days.

Treatment of Blood Count Abnormalities: If evidence of significant bone marrow depression develops, the following recommendations are suggested: (1) stop the drug, (2) perform daily CBC, platelet and reticulocyte counts, (3) do a bone marrow aspiration and trephine biopsy immediately and repeat with sufficient frequency to monitor recovery.

Special periodic studies might be helpful as follows: (1) white cell and platelet antibodies, (2) 59Fe—ferrokinetic studies, (3) peripheral blood cell typing, (4) cytogenetic studies on marrow and peripheral blood, (5) bone marrow culture studies for colony-forming units, (6) hemoglobin electrophoresis for A_2 and F hemoglobin, and (7) serum folic acid and B_{12} levels.

A fully developed aplastic anemia will require appropriate, intensive monitoring and therapy, for which specialized consultation should be sought.

DOSAGE AND ADMINISTRATION

Monitoring of blood levels has increased the efficacy and safety of anticonvulsants (see PRECAUTIONS, Laboratory Tests). Dosage should be adjusted to the needs of the individual patient. A low initial daily dosage with a gradual increase is advised. As soon as adequate control is achieved, the dosage may be reduced very gradually to the minimum effective level. Tablets should be taken with meals.

Epilepsy (see INDICATIONS AND USAGE).

Adults and children over 12 years of age—Initial: 200 mg b.i.d. Increase at weekly intervals by adding up to 200 mg per day using a t.i.d. or q.i.d. regimen until the best response is obtained. Dosage should generally not exceed 1000 mg daily in children 12 to 15 years of age, and 1200 mg daily in patients above 15 years of age. Doses up to 1600 mg daily have been used in adults in rare instances. ***Maintenance:*** Adjust dosage to the minimum effective level, usually 800-1200 mg daily.

Children 6-12 years of age—Initial: 100 mg b.i.d. Increase at weekly intervals by adding 100 mg per day using a t.i.d. or q.i.d. regimen until the best response is obtained. Dosage should generally not exceed 1000 mg. ***Maintenance:*** Adjust dosage to the minimum effective level, usually 400-800 mg daily.

Combination Therapy: Tegretol may be used alone or with other anticonvulsants. When added to existing anticonvulsant therapy, the drug should be added gradually while the other anticonvulsants are maintained or gradually decreased, except phenytoin, which may have to be increased (see PRECAUTIONS, Drug Interactions and Pregnancy Category C).

Trigeminal Neuralgia (see INDICATIONS AND USAGE).

Initial: 100 mg b.i.d. on the first day for a total daily dose of 200 mg. This daily dose may be increased by up to 200 mg a day using increments of 100 mg every 12 hours only as needed to achieve freedom from pain. Do not exceed 1200 mg daily.

Maintenance: Control of pain can be maintained in most patients with 400 mg to 800 mg daily. However, some patients may be maintained on as little as 200 mg daily, while others may require as much as 1200 mg daily. At least once every 3 months throughout the treatment period, attempts should be made to reduce the dose to the minimum effective level or even to discontinue the drug.

HOW SUPPLIED

Chewable Tablets 100 mg—round, red-speckled, pink, single-scored (imprinted Tegretol on one side and 52 twice on the scored side)

Bottles of 100	NDC 58887-052-30
Unit Dose (blister pack)	
Box of 100 (strips of 10)	NDC 58887-052-32

Tablets 200 mg—capsule-shaped, pink, single-scored (imprinted Tegretol on one side and 27 twice on the scored side)

Bottles of 100	NDC 58887-027-30
Bottles of 1000	NDC 58887-027-40
Unit Dose (blister pack)	
Box of 100 (strips of 10)	NDC 58887-027-32

Samples, when available, are identified by the word *SAMPLE* appearing on each tablet.

Protect from moisture.

Dispense in tight container (USP).

Also available as: Tegretol suspension 100 mg/5 ml, in 450 ml bottles

Printed in U.S.A. C91-18 (Rev. 9/91

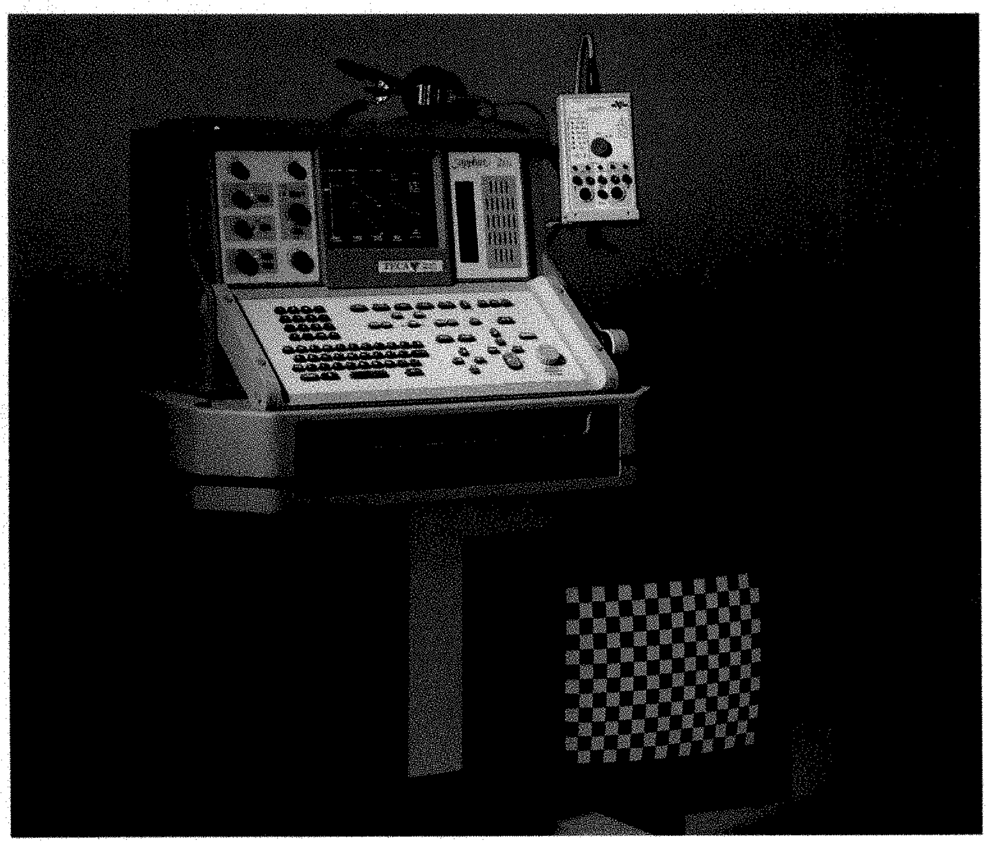
EMG/EP FOR THE 90'S FROM TECA



In the 90's two seemingly disparate terms – **advanced technology and affordability–** were linked when TECA announced the Sapphire line of portable EMG/EP instruments. Sapphire delivers all the advantages of modern technology with pricing that is realistic in today's economic environment.

- Superfast real-time EMG
- 1 or 2 channels
- EP stims
- Automatic NCV studies
- 10 seconds of EMG memory
- Trigger and delay line
- 16 programmable tests
- High resolution 12 bit A/D
- Trace annotation
- Disk drive and reporting
- Fast thermal printout

The Sapphire range is available from a single channel EMG instrument, to a full function EMG with Evoked Potentials. All routine tests are performed at the push of a button.

TECA Corporation, in the forefront with innovative instrumentation and a reputation for quality and service for over 40 years.

Instructions for Authors

Send manuscripts by first-class mail to the Chief Editor, Robert J. Joynt, MD, PhD, University of Rochester School of Medicine and Dentistry, 601 Elmwood Ave, Rochester, NY 14642. Manuscripts are received with the understanding that they are not under simultaneous consideration by another publication. Accepted manuscripts become the permanent property of the ARCHIVES and may not be published elsewhere without permission from the publisher (AMA).

Cover Letter.—Designate one author as correspondent and provide a complete address and telephone number.

In the cover letter include (1) statement on authorship responsibility, (2) statement on financial disclosure, and (3) one of the two following statements on copyright *or* federal employment. Each of these three statements must be signed by *all* authors.

1. Authorship Responsibility.—"I certify that I have participated sufficiently in the conception and design of this work and the analysis of the data (when applicable), as well as the writing of this manuscript, to take public responsibility for it. I believe the manuscript represents valid work. I have reviewed the final version of the manuscript and approve it for publication. Neither this manuscript nor one with substantially similar content under my authorship has been published or is being considered for publication elsewhere, except as described in an attachment. Furthermore, I attest that I shall produce the data upon which the manuscript is based for examination by the editors or their assignees if requested."

2. Financial Disclosure.—"I certify that affiliations (if any) with or involvement in any organization or entity with a direct financial interest in the subject matter or materials discussed in the manuscript (eg, employment, consultancies, stock ownership, honoraria, expert testimony) are disclosed below."

Research or project support should be listed in an acknowledgement.

3a. Copyright Transfer.—"In consideration of the action of the American Medical Association (AMA) in reviewing and editing this submission, the author(s) undersigned hereby transfer(s) assign(s), or otherwise convey(s) all copyright ownership to the AMA in the event that such work is published by the AMA."

3b. Federal Employment.—"I was an employee of the US federal government when this work was investigated and prepared for publication; therefore, it is not protected by the Copyright Act and there is no copyright of which the ownership can be transferred."

We regret that transmittal letters not containing the preceding language signed by all authors of the submission will necessitate delay in review of the manuscript.

Editing.—All accepted manuscripts are subject to copy editing. The author will receive an edited typescript rather than galley proofs for approval. The author is responsible for all statements in his work, including changes made by the copy editor.

Order reprints at the time the typescript is returned after editorial processing. Specify address to which requests for reprints should be sent.

Manuscript Preparation.—Submit three high-quality copies of the entire manuscript. The copies will not be returned. The authors should keep the original manuscript for submission if accepted. The original manuscript (including references, legends, and tables) must be typed double-spaced on 21.6 × 27.9-cm 8½ × 11-in), heavy-duty white bond paper. Ample margins of at least 2.5 cm (1 in) should be provided. **If a word processor is used, do not justify right-hand margins.**

Refer to patients by number (or, in anecdotal reports, by fictitious given names). Real names or initials should not be used in the text, tables, or illustrations.

Titles.—Titles should be short, specific, and clear. They should not exceed 42 characters per line, including punctuation and spaces, and be limited to two lines, if possible. The title page should include the full names and academic affiliations of all authors, and the address to which requests for reprints should be sent.

Style of Writing.—The style of writing should conform to acceptable English usage and syntax. Slang, medical jargon, obscure abbreviations, and abbreviated phrasing are to be avoided.

Informed Consent.—Manuscripts reporting the results of experimental investigations of human subjects must include a statement to the effect that informed consent was obtained after the nat of the procedure(s) had been fully explained.

Abstract.—Provide an abstract (135-word maximum) of article, including statements of the problem, method of stu results, and conclusions. The abstract replaces the summary.

References.—List references in consecutive numerical order (alphabetically). Once a reference is cited, all subsequent citati should be to the original number. All references must be cite the text or tables. Unpublished data and personal communicati should not be listed as references. References to journal arti should include (1) author(s) (list all authors and/or editors u six; if more than six, list the first three and "et al"), (2) title, journal name (as abbreviated in *Index Medicus*), (4) year, (5) ume number, and (6) inclusive page numbers, in that order. Ref ences to books should include (1) author(s) (list all authors and editors up to six; if more than six, list the first three and "et a (2) chapter title (if any), (3) editor (if any), (4) title of book, (5) of publication, (6) publisher, and (7) year. Volume and edit numbers, specific pages, and name of translator should be inclu when appropriate. **The author is responsible for the accuracy and c pleteness of the references and for their correct text citation.**

SI Units.—Use Système International (SI) measureme throughout the manuscript. (See June 1986 issue of ARCHIVES.)

Illustrations.—The illustrations originally submitted will not returned. High-quality copies may be used. Original illustrati should be kept by the author for submission if the manuscrip accepted. Use only those illustrations that clarify and augm the text. If accepted, submit illustrations in triplicate, unmoun and untrimmed. Do not send original artwork. Send high-contr glossy prints (not photocopies). Figure number, name of sen author, and arrow indicating "top" should be typed on a gumm label and affixed to the back of each illustration. All letteri must be legible after reduction to column size. Artwork submit for publication may be relettered to achieve uniformity of lett ing style throughout the journal. Magnification and stain sho be provided when pertinent. Illustrations should preferably be a proportion of 12.7 × 7.3 cm (5 × 7 in).

Template lettering or preset type is preferred to hand-lette labels. If halftone artwork with labels is submitted, affix type a leaders to a clear acetate overlay registered to the base drawi Labels and leaders should be applied directly to the drawing boa surface if the artwork consists only of line ink technique.

Illustrations in full color are accepted for publication if t editors believe that color will add significantly to the publish manuscript. The ARCHIVES will pay part of the expense of rep duction and printing color illustrations, the remainder to be bor by the author or his sponsor. After deducting the ARCHIV contribution, the author's share is $400 for up to six squa finished illustrations that can be arranged on a one-page layo Any additional illustrations or special effects will be billed to t author at cost. Positive color transparencies (35 mm preferre must be submitted for an evaluation. Do not send color pri unless accompanied by original transparencies. All transparenci should be carefully packed and sent with the manuscript.

Legends.—Legends should be typed double-spaced, beginning a separate sheet of paper. Length should be limited to a maximu of 40 words.

Photographic Consents.—A letter of consent must accompany photographs of patients in which a possibility of identificati exists. It is not sufficient to cover the eyes to mask identity.

Acknowledgments.—Illustrations from other publications mu be acknowledged. Include the following when applicab author(s), title of article, title of journal or book, volume numb page(s), month, and year. The publisher's permission to repri should be submitted to the ARCHIVES after the manuscript h been formally accepted.

Statistical Review.—Manuscripts containing statistical evalu tions should include the name and affiliation of the statistic reviewer.

Tables.—Each table should be typed double-spaced, including a headings, on a separate sheet of 21.6 × 27.9-cm (8½ × 11-i paper. Do not use larger size paper. If a table must be continue use a second sheet and repeat all heads and stubs. Each table mu have a title.

Calendar

CALENDAR OF MEETINGS

1991		
Oct	21-22	The Second International Immunobiology of Renal Cell Carcinoma Symposium, Ritz-Carlton Hotel, Cleveland, Ohio. Contact The Cleveland Clinic Educational Foundation, Department of Continuing Education, PO Box 94977, Cleveland, OH 44195-5241; (216) 444-5696; (800) 762-8173 outside Ohio.
Nov	6-10	"Progress in Understanding Postconcussion Syndrome," Four Seasons Hotel, Dallas, Tex. Contact Ann McCormick, Southern California Neuropsychiatric Institute, 6794 La Jolla Blvd, La Jolla, CA 92037; (619) 454-2102.
	8	"Contemporary Concepts of Headache Management for the Neurologist," Farmington, Conn. Contact Susan Crawford, Neurology Department, University of Connecticut School of Medicine, 263 Farmington Ave, Farmington, CT 06030; (203) 679-3186.
	16	"Selegiline: New Applications in Neurological and Psychiatric Disorders," New York, NY. Contact New York University Medical Center, Postgraduate Medical School, 550 First Ave, New York, NY 10016; (212) 263-5295.
	22-24	Second International Headache Research Seminar, Copenhagen, Denmark. Contact Mrs Vibe Halling, Secretary, Second International Headache Research Seminar, Department of Neurology, Gentofte Hospital, Niels Andersens Vej 65, DK-2900 Hellerup, Copenhagen, Denmark.
	27-31	International Symposium on Cerebrovascular Disorders, Goiana-Goiás, Brazil.
Dec	6	"Current Neuro-Ophthalmology," Ritz-Carlton Buckhead, Atlanta, Ga. Contact Emory University School of Medicine, Office of Continuing Medical Education, 1440 Clifton Rd, Atlanta, GA 30322; (404) 727-5695.
	6-7	"Molecular and Cellular Approaches to the Treatment of Brain Disease," Penta Hotel, New York, NY. Contact Ivan Bodis-Wollner, MD, Box 1052, Association for Research in Nervous and Mental Disease, Mount Sinai Hospital, One Gustave L. Levy Pl, New York, NY 10029; (212) 348-8133.

Stay Ahead of the Headlines

Principles of Drug Therapy in Neurology will bring you up-to-date on the latest research affecting neurologic practice today.

Neurology for the 90s.

Once considered largely untreatable, neurologic disorders have become the newest frontier for breakthrough research in pharmacology. *Principles of Drug Therapy in Neurology* discusses the latest investigational strategies and theories and how they affect current clinical practice. This new book brings you up-to-date on the latest neurologic drugs and treatments, and helps you stay ahead in this demanding field.

Comprehensive, Concise Treatment of Current Drug Use in Neurology.

From the latest approaches to Alzheimer's disease to the pharmacology of "crack cocaine," this new book details the mechanisms, delivery systems, and efficacy of the latest medications. *Principles of Drug Therapy in Neurology* bridges the gap between the experimental and the practical, and lets you get a jump on the issues and answers in neurology today.

CONTEMPORARY NEUROLOGY SERIES

Contemporary Neurology Series, No. 37
Approx. 380 pages
Illustrated
November 1991
Approx. $75.00

Contents: A solid balance between the practical and the theoretical.

Chapter 1. Fundamentals of Drug Therapy in Neurology. Molecular Targets of Drug Action in the Nervous System. Barriers to Drug Action in the CNS. Dynamic Features of Drug Action. Toxicity of Neuroactive Drugs. Influence of Age on Drug Action. ***Chapter 2. Movement Disorders.*** Neurochemical Anatomy of Basal Ganglia. Parkinson's Disease. Huntington's Disease. Dystonia. Tremors. Tics. Hemiballismus. Spasticity. Wilson's Disease. Drug Manipulation of Transmitter Systems. ***Chapter 3. Seizure Disorders and Epilepsy.*** Seizures and Epilepsies. Clinical Classification of Anticonvulsant Drugs. Mechanisms of Action of Anticonvulsant Drugs. Mechanistic Classification of Anticonvulsant Drugs. Clinical Use of Anticonvulsant Drugs for Chronic Therapy. Therapy for Status Epilepticus. ***Chapter 4. Hypoxic-Ischemic Disorders and Stroke.*** Background. Therapies to Enhance Brain Oxygen and Substrate Supply. Experimental Therapies to Maintain Cellular Viability. Therapies for Stroke Edema. Selection of Established Pharmacotherapies. ***Chapter 5. Migraine.*** Theories of Migraine Pathogenesis. Pharmacological Approaches to Migraine. Future Approaches. ***Chapter 6. Immune-Mediated Disorders.*** Organization of Immune System. CNS/Immune System Interactions. Autoimmune Neurologic Diseases. Immunotherapies. Immunotherapy in Human Autoimmune Neurologic Disease. ***Chapter 7. Psychiatric Disorders.*** Clinical Psychopharmacology. Neuroleptics. Antidepressants. Benzodiazepines. ***Chapter 8 Cognitive Disorders.*** Memory Disorders. Dementia. Therapy for Dementia. Cognitive Disorders in Young People. ***Chapter 9. Pain.*** Introduction to Clinical Pain and Its Management. Anatomy and Physiology of Central Nociceptive Systems. Antinociceptive Systems in the CNS. Pharmacological Management of Pain. ***Chapter 10. Acute Drug Intoxication and Abuse.*** Alterations in Consciousness Caused by Drugs and Toxins. Seizures Caused by Drug Intoxication.

Authors and editors bring a unique blend of clinical and experimental perspectives.

Michael V. Johnston, M.D.
Professor and Haller Scholar of Neurology and Pediatrics. Johns Hopkins University School of Medicine and the Kennedy Institute, Baltimore, Maryland.

Robert L. Macdonald, M.D., Ph.D.
Professor of Neurology and Physiology, University of Michigan Medical School, Ann Arbor, Michigan.

Anne B. Young, M.D., Ph.D.
Professor and Chief, Neurology Service, Massachusetts General Hospital and Julieanne Dorn Professor of Neurology, Harvard Medical School, Boston, Massachusetts.

Books

Clinical Neurophysiology Update, edited by J. E. Desmedt, vol 1, **Neuromonitoring in Surgery,** 377 pp, with illus; vol 2, **Computer-Aided Electromyography and Expert Systems,** 320 pp, with illus, Amsterdam, the Netherlands, Elsevier, 1989.

This series, edited by Professor Desmedt, who has been very active in the field of clinical neurophysiology for many years, follows the first series, *Clinical Neurophysiology,* published in 1973, and the second series, *Clinical Neurophysiology Progress,* published in 1981.

Volume 1 contains 20 chapters written by world authorities dealing with neuromonitoring techniques in surgery. This field has been developing rapidly because of new technology and is very important in surgical interventions on brain, spinal cord and roots, and peripheral nerves. The techniques help the operating team to assess function during a procedure to avoid neurologic damage. These new neuromonitoring techniques require the training of a new group of neuroanesthesiologists-clinical neurophysiologists, who can document preservation of neural function during difficult surgical procedures. This area of clinical neurophysiology should continue to develop and already has shown its value in surgical therapy. Included in this volume are chapters dealing with somatosensory evoked potentials, auditory nerve and brain-stem responses, transcranial stimulation, neuromuscular transmission, peripheral nerve recordings, spinal cord potentials, and seizure monitoring. The techniques are well-described and illustrated. Experience and results of using the techniques in various diseases and procedures are presented. A large reference list is provided at the end of the volume. This volume is highly recommended to all physicians, physiologists, and technicians who are interested in neurologic function and how it may be altered during surgical procedures. All clinical neurophysiology laboratories should be using these techniques, and this volume will be helpful in their use and interpretation.

Volume 2 stresses computers and new technology in the study and analysis of electromyelographic (EMG) signals and its value in neuromuscular disease. Each of the 23 chapters is written by world authorities in the area. The volume is divided into sections on needle EMG motor-unit recordings, surface EMG, EMG-interference patterns, applications of EMG analysis and artificial intelligence, and expert systems in neuromuscular diagnosis. The chapters are well written and have adequate illustrations. The reference list is comprehensive and located at the end of the volume.

Quantitative EMG has been available for many years and depends on technology as well as the ease of its use and the dependability of its results. Most laboratories using these techniques are now research oriented, since the techniques, to date, have not been reliable by themselves for accurate neuromuscular diagnoses or therapy. However, they remain important in the physiologic study and interpretation of neuromuscular function. This volume is recommended for students, engineers, and clinical neurophysiologists who are active in this area of research. Clinical neurologists will not find it helpful in their practice at this time.

RICHARD F. MAYER, MD
Baltimore, Md

Textbook of Performing Arts Medicine, edited by Robert Thayer Sataloff, Alice G. Brandfonbrener, and Richard J. Lederman, 432 pp, with illus, $88, New York, NY, Raven Press, 1991.

The publication of *Textbook of Performing Arts Medicine* marks another milestone in the growth of this new multidisciplinary specialty, complementing the recent arrivals of annual conferences, peer-reviewed journals, and professional societies. The editors of this concise volume are among the leaders in the field, Lederman being one of the leading neurologists in performing arts medicine. Since the field is still relatively early in its evolution, often there is a dearth of scientific data on which to base clinical practice. The authors and editors have done an admirable job of combining the available literature with their own considerable experience to produce a very useful text.

The 15 chapters are all well referenced and well illustrated. The major clinical entities in performing arts medicine—musculoskeletal pain syndromes and neurologic impairment of the upper extremities in instrumentalists, voice problems in singers, and lower extremity injuries in dancers—are covered well in several of the longer chapters. The chapter on voice care includes a suggested clinical database for the singer with problems. A similar outline for the hurting instrumentalist would have been helpful; the recommended workup is spread out over three chapters. The discussion of neurologic problems is comprehensive and covers both performance-induced and other performance-impairing conditions.

Three chapters are devoted to the psychological problems of performers, but this book does not offer a consolidated review of performance anxiety. Several other relevant topics are reviewed in other chapters: eye problems and hearing loss, reproductive difficulties among female dancers, and temporomandibular joint problems. The book opens nicely with a historical review of the development of the field and an epidemiologic overview of performers' problems. The closing chapter, on legal aspects of the health care of performers, is devoted almost entirely to malpractice issues. A discussion of workers' compensation issues would have been relevant here. An index is provided.

This book should become the standard reference for clinicians in a variety of specialties who see performing artists, especially musicians. Use of the book does not presuppose a sophisticated knowledge of music or dance. Whether it will be used by performers and their teachers remains to be seen. One hopes that it will enhance the interaction between performers and those who care for them.

RALPH A. MANCHESTER, MD
Rochester, NY

Neck and Arm Pain, ed 3, by R. Cailliet, 226 pp, $16.95, Philadelphia, Pa, FA Davis Co Publishers, 1991.

This work addresses the evaluation and treatment of commonly encountered symptoms in the general practice of medicine. The early chapters are concerned with anatomy, cervical nerves, and posture. The analysis of symptoms based on pain mechanisms is well prepared and focused on the diverse structures within the cervical spine and spinal cord that may be the source of pain. The section dedicated to whiplash syndrome is well done, and the author's approach to different types of treatment is nicely presented. All of the chapters contain numerous, well-drawn illustrations by Dr Cailliet. Unfortunately, at times they are presented on pages that do not correspond to the actual text. The chapters concerned with spondylitic myelopathy and thoracic outlet syndrome pay little attention to possible surgical intervention.

The bibliography at the end of each chapter is substantial and current.

This short, focused work contains much useful information that should be most helpful to a wide group of health professionals.

RICHARD SATRAN, MD
Rochester, NY

Advances in Neurology, volume 55, **Neurobehavioral Problems in Epilepsy**, edited by Dennis B. Smith, David M. Treiman, and Michael R. Trimble, 485 pp, $135, New York, NY, Raven Press, 1990.

The *Advances in Neurology* series has been delivering useful, state-of-the-art reviews of clinical topics for almost 20 years. This, the 55th volume in the series, is quite in keeping with the high standards that have been established. The volume belongs in the library of all behavioral neurologists, epileptologists, and clinicians who have a substantial commitment to treatment of, and research in, epilepsy.

Does epilepsy predispose to violence? To psychosis? What is our current understanding of the interictal personality disorders of epilepsy? Is carbamazepine *really* "easier" on cognition than its competitors? Which anticonvulsants are psychotropics, and how valuable are they in actual practice? These controversies and others receive measured consideration within the chapters of this book. For example, with regard to the question of interictal behavioral disturbances that develop among patients with temporal lobe epilepsy, the contrasting viewpoints of Janice Stevens, Michael Trimble, and Frank Benson are all presented. Jerome Engel provides a complementary review of more basic physiologic and animal research of relevance to the issue. The book does not attempt to provide a synthesis of these divergent perspectives but lets these senior scholars speak for themselves.

There is a solid, international character to the list of contributors, and most speak with the authority of academic centers, where there is ongoing neuropsychiatric research into behavioral aspects of epilepsy. The UCLA group is well represented among the authorship as well as the National Institute of Mental Health, Bethesda, Md, and the National and Maudsley Hospitals, London, England. German, Swiss, and French groups are also represented. References for most chapters are encyclopedic. The quality of presentation by the publisher is high, and few typographical errors have slipped by the editors.

At this juncture in the review, I would normally add some comments about weaknesses and failings in the book. For *Neurobehavioral Problems in Epilepsy* I have none. This book is well done, topical, and valuable to researchers and clinicians alike. It should serve a wide audience and come to be widely cited.

RANDOLPH B. SCHIFFER, MD
Rochester, NY

Peripheral Neuropathy in Childhood, by R. Ouvrier, J. G. McLeod, and J. Pollard, 252 pp, $84, New York, NY, Raven Press, 1990.

Neuropathies in children are uncommon and often nettlesome clinical problems. Because these slowly evolving disorders can produce pes cavus or scoliosis before their neuropathic nature is appreciated, these children are likely to be seen by pediatricians and orthopedists long before they are referred to neurologists. Most neurologists have limited experience with childhood neuropathies and will welcome the advent of this readable, slender, and focused resource. The authors have long-standing and broadly based interests in the childhood neuropathies. Dr Ouvrier, the pediatric neurologist at Children's Hospital Camperdown, Sydney, Australia, has worked for years with his colleagues at the University of Sydney. Drs McLeod and Pollard are leading figures in the clinical, physiological, and pathological assessment of neuropathies. The resulting volume covers in an authoritative fashion the major heritable neuropathies and the inflammatory demyelinating neuropathies. It more briefly presents the rare metabolic and idiopathic conditions. Adequate attention is directed toward the organization, pathophysiology, and clinical assessment of peripheral nerves so that the descriptions of abnormalities in individual diseases can be followed by the nonspecialist and the nonneurologist. Thus, while this book will be read through by pediatric neurologists and by neuromuscular specialists, it undoubtedly will be useful to pediatricians, orthopedists, and house staff in their evaluation of individual patients.

After the introductory chapters, the book is organized by diseases. Written in a straightforward style, the text has a formality that recalls earlier times. For example, at the end of several discussions, "Case Histories," some credited to colleagues, are effectively presented in a fashion reminiscent of Weir Mitchell. This leisurely and attractive feature contrasts with the brevity with which some disorders of particular current interest are presented. For example, mitochondrial cytopathies are dismissed in one sentence, and no mention of the explosion of clinically useful molecular approaches in the heritable amyloidoses is offered.

This is a cautious book. The literature is extensively cited and controversies are dutifully noted. At times, the reader may wish that the authors were not quite so dutiful and evenhanded. The preface suggests that "this book is written from a strong personal perspective based, where possible, on our own clinical experience. It is likely that some will disagree with our experience, but when possible we prefer to state an opinion and have it refuted rather than to equivocate." This warning may refer to the authors' firm stance that Dejerine-Sottas disease is a distinct recessive disorder with characteristic features and to the attention given to "Hereditary Motor and Sensory Neuropathy of Neuronal Type With Onset in Early Childhood" (the latter is a disorder in need of an acro-, epo-, or other short "nym"). These are disorders about which Dr Ouvrier has contributed original work, and the discussions make clear the authors' views. However, in other areas, despite their extensive experience, they are content to cite opinions and data from the literature. For example, their experience with 60 cases of childhood Guillain-Barré syndrome is not further detailed or called on to support opinions. Their experience would have been welcome.

Finally, this book has the advantage of its Australian origins and reflects the sharing of information and the concentration of experience that characterize the Australian health system. The authors explicitly acknowledge cases and data from other Australian workers, particularly Dr Lloyd Shield in Melbourne, and implicitly acknowledge the Australian system that (in common with the British, Canadian, and New Zealand systems) allows the collection of specific diseases and problems in centers. The authors undoubtedly see most of the pediatric peripheral nerve disease in New South Wales. Whatever defects these health care systems might have, they encourage the referral and central collection of material from rare disorders. Few individuals in this country have had such experience with peripheral nerve disease in children, and, with the continued dissemination of subspecialty expertise, even fewer will in the future. This book will remain a useful clinical resource.

JOHN W. GRIFFIN, MD
Baltimore, Md

ANNUAL MEETING AND COURSES

American Electroencephalographic Society
December 10-14, 1991
Philadelphia, Pennsylvania

The **Annual Meeting** of the Society will be held December 10-12 at the Wyndham Franklin Plaza Hotel in Philadelphia, Pennsylvania. The program will include Symposia on: **The Changing Contribution of Electrophysiology to Epileptology**, **EEG-Neurophysiology-Epileptogenesis**, and **Advances in Evoked Potentials**, as well as Scientific Sessions, posters, and a technical exhibit.

The **Annual Courses** of the Society will be held December 13 and 14 at the Wyndham Franklin Plaza. Courses include: **Basic EEG** (full-day), **Neonatal EEG**, **Technology of EEG**, **Polysomnography**, and **Evoked Potentials**.

The American EEG Society is accredited by the Accreditation Council for Continuing Medical Education to sponsor continuing medical education for physicians.

PERMAX®

pergolide mesylate

An added dimension in the treatment of Parkinson's disease

An adjunct to levodopa/carbidopa in the management of patients with Parkinson's disease

- The first dopamine agonist indicated for Parkinson's disease with activity at both D_1 and D_2 receptors
- 10 to 1,000 times more potent than bromocriptine on a milligram-per-milligram basis
- Improves patients' functioning in activities of daily living, relieves signs and symptoms, and reduces "off" time
- May allow a significant reduction in levodopa dosage
- Most common adverse events were dyskinesia, nausea, dizziness, and hallucinations
- Hypotension may occur, especially early in the course of therapy
- Stepwise titration without regard to meals
- Available in 0.05-mg, 0.25-mg, and 1-mg scored tablets

Permax performs

Artist's conception of dopamine agonism in the synapse
See adjacent page for prescribing information.

Permax®

pergolide mesylate

Brief Summary. Consult the package insert for complete prescribing information.

Indications and Usage: Permax is indicated as adjunctive treatment to levodopa/carbidopa in the management of the signs and symptoms of Parkinson's disease.

Evidence to support the efficacy of pergolide mesylate as an antiparkinsonian adjunct was obtained in a multicenter study enrolling 376 patients with mild to moderate Parkinson's disease who were intolerant to levodopa/carbidopa as manifested by moderate to severe dyskinesia and/or on-off phenomena. On average, the sample of patients evaluated had been on levodopa/carbidopa for 3.9 years (range, two days to 16.8 years). The administration of pergolide mesylate permitted a 5% to 30% reduction in the daily dose of levodopa. On average, these patients treated with pergolide mesylate maintained an equivalent or better clinical status than they exhibited at baseline.

Contraindications: Pergolide mesylate is contraindicated in patients who are hypersensitive to this drug or other ergot derivatives.

Warnings: *Symptomatic Hypotension* —In clinical trials, approximately 10% of patients taking pergolide mesylate with levodopa vs 7% taking placebo with levodopa experienced symptomatic orthostatic and/or sustained hypotension, especially during initial treatment. With gradual dosage titration, tolerance to the hypotension usually develops. It is, therefore, important to warn patients of the risk, to begin therapy with low doses, and to increase the dosage in carefully adjusted increments over a period of three to four weeks.

Hallucinosis —In controlled trials, pergolide mesylate with levodopa caused hallucinosis in about 14% of patients as opposed to 3% taking placebo with levodopa. This was of sufficient severity to cause discontinuation of treatment in about 3% of those enrolled; tolerance to this untoward effect was not observed.

Fatalities —In the placebo-controlled trial, two of 187 patients treated with placebo died as compared with one of 189 patients treated with pergolide mesylate. Of the 2,299 patients treated with pergolide mesylate in premarketing studies evaluated as of October 1988, 143 died while on the drug or shortly after discontinuing the drug. The patient population under evaluation was elderly, ill, and at high risk for death. It seems unlikely that pergolide mesylate played any role in these deaths, but the possibility that pergolide shortens survival of patients cannot be excluded with absolute certainty.

In particular, a case-by-case review of the clinical course of the patients who died failed to disclose any unique set of signs, symptoms, or laboratory results that would suggest that treatment with pergolide caused their deaths. Sixty-eight percent (68%) of the patients who died were 65 years of age or over. No death (other than a suicide) occurred within the first month of treatment; most of the patients who died had been on pergolide for years. A relative frequency of the causes of death by organ system are: pulmonary failure/pneumonia, 35%; cardiovascular, 30%; cancer, 11%; unknown, 8.4%; infection, 3.5%; extrapyramidal syndrome, 3.5%; stroke, 2.1%; dysphagia, 2.1%; injury, 1.4%; suicide, 1.4%; dehydration, 0.7%; glomerulonephritis, 0.7%.

Precautions: *General* —Caution should be exercised when administering pergolide mesylate to patients prone to cardiac dysrhythmias.

In a study comparing pergolide mesylate and placebo, patients taking pergolide mesylate were found to have significantly more episodes of atrial premature contractions (APCs) and sinus tachycardia.

The use of pergolide mesylate in patients on levodopa may cause and/or exacerbate preexisting states of confusion and hallucinations (*see* Warnings). Also, the abrupt discontinuation of pergolide mesylate in patients receiving it chronically as an adjunct to levodopa may precipitate the onset of hallucinations and confusion; these may occur within a span of several days. Discontinuation of pergolide should be undertaken gradually whenever possible, even if the patient is to remain on levodopa.

The administration of pergolide mesylate to patients receiving levodopa may cause and/or exacerbate preexisting dyskinesia.

Information for Patients —Patients and their families should be informed of the common adverse consequences of the use of pergolide mesylate (*see* Adverse Reactions) and the risk of hypotension (*see* Warnings).

Patients should be advised to notify their physician if they become pregnant or intend to become pregnant during therapy.

Patients should be advised to notify their physician if they are breast feeding an infant.

Laboratory Tests —No specific laboratory tests are deemed essential for the management of patients on Permax. Periodic routine evaluation of all patients, however, is appropriate.

Drug Interactions —Dopamine antagonists, such as the neuroleptics (phenothiazines, butyrophenones, thioxanthines) or metoclopramide, ordinarily should not be administered concurrently with Permax (a dopamine agonist); these agents may diminish the effectiveness of Permax.

Because pergolide mesylate is approximately 90% associated with plasma proteins, caution should be exercised if pergolide mesylate is coadministered with other drugs known to affect protein binding.

Carcinogenesis, Mutagenesis, and Impairment of Fertility —A two-year carcinogenicity study was conducted in mice using dietary levels of pergolide mesylate equivalent to oral doses of 0.6, 3.7, and 36.4 mg/kg/day in males and 0.6, 4.4, and 40.8 mg/kg/day in females. A two-year study in rats was conducted using dietary levels equivalent to oral doses of 0.04, 0.18, and 0.88 mg/kg/day in males and 0.05, 0.28, and 1.42 mg/kg/day in females. The highest doses tested in the mice and rats were approximately 340 and 12 times the maximum human oral dose administered in controlled clinical trials (6 mg/day equivalent to 0.12 mg/kg/day).

A low incidence of uterine neoplasms occurred in both rats and mice. Endometrial adenomas and carcinomas were observed in rats. Endometrial sarcomas were observed in mice. The occurrence of these neoplasms is probably attributable to the high estrogen/progesterone ratio which would occur in rodents as a result of the prolactin-inhibiting action of pergolide mesylate. The endocrine mechanisms believed to be involved in the rodents are not present in humans. However, even though there is no known correlation between uterine malignancies occurring in pergolide-treated rodents and human risk, there are no human data to substantiate this conclusion.

Pergolide mesylate was evaluated for mutagenic potential in a battery of tests that included an Ames bacterial mutation assay, a DNA repair assay in cultured rat hepatocytes, a point-mutation assay in cultured L5178Y cells, and a determination of chromosome alteration in bone marrow cells of Chinese hamsters. A weak mutagenic response was noted in the in vitro mammalian cell-point-mutation assay using L5178Y cells only after metabolic activation with rat liver microsomes. No mutagenic effects were obtained in the two other in vitro assays and in the in vivo assay. The relevance of these findings to humans is unknown.

A fertility study in male and female mice showed that fertility was maintained at 0.6 and 1.7 mg/kg/day but decreased at 5.6 mg/kg/day. Prolactin has been reported to be involved in stimulating and maintaining progesterone levels required for implantation in mice and, therefore, the impaired fertility at high dose may occur because of depressed prolactin levels.

Usage in Pregnancy - Pregnancy Category B —Reproduction studies were conducted in mice at doses of 5, 16, and 45 mg/kg/day and in rabbits at doses of 2, 6, and 16 mg/kg/day. The highest doses tested in mice and rabbits were 375 and 133 times the 6 mg/day maximum human dose administered in controlled clinical trials. In these studies, there was no evidence of harm to the fetus due to pergolide mesylate.

PR-9002-2 T-149308 © 1991 ELI LILLY AND COMPANY

There are, however, no adequate and well-controlled studies in pregnant women. Among women who received pergolide mesylate for endocrine disorders in premarketing studies, there were 33 pregnancies that resulted in healthy babies and four pregnancies that resulted in congenital abnormalities (two major, two minor); a causal relationship has not been established. Because human data are limited and because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nursing Mothers —It is not known whether this drug is excreted in human milk. The pharmacologic action of pergolide mesylate suggests that it may interfere with lactation. Because many drugs are excreted in human milk and because of the potential for serious adverse reactions to pergolide mesylate in nursing infants, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use —Safety and effectiveness in children have not been established.

Adverse Reactions: *Commonly Observed* —In premarketing clinical trials, the most commonly observed adverse events associated with use of pergolide mesylate which were not seen at an equivalent incidence among placebo-treated patients were: nervous system complaints, including dyskinesia, hallucinations, somnolence, insomnia; digestive complaints, including nausea, constipation, diarrhea, dyspepsia; and respiratory system complaints, including rhinitis.

Associated With Discontinuation of Treatment —Twenty-seven percent (27%) of approximately 1,200 patients receiving pergolide mesylate for treatment of Parkinson's disease in premarketing clinical trials in the US and Canada discontinued treatment due to adverse events. The events most commonly causing discontinuation were related to the nervous system (15.5%), primarily hallucinations (7.8%) and confusion (1.8%).

Fatalities - *See* Warnings.

Incidence in Controlled Clinical Trials —The table that follows enumerates adverse events that occurred at a frequency of 1% or more among patients taking pergolide mesylate who participated in the premarketing controlled clinical trials comparing pergolide mesylate with placebo. In a double-blind, controlled study of six months' duration, patients with Parkinson's disease were continued on levodopa/carbidopa and were randomly assigned to receive either pergolide mesylate or placebo as additional therapy.

The prescriber should be aware that these figures cannot be used to predict the incidence of side effects in the course of usual medical practice where patient characteristics and other factors differ from those which prevailed in the clinical trials. Similarly, the cited frequencies cannot be compared with figures obtained from other clinical investigations involving different treatments, uses, and investigators. The cited figures, however, do provide the prescribing physician with some basis for estimating the relative contribution of drug and nondrug factors to the side-effect incidence rate in the population studied.

Incidence of Treatment-Emergent Adverse Experiences in the Placebo-Controlled Clinical Trial

*Events reported by at least 1% of patients receiving pergolide mesylate are included.

Events Observed During the Premarketing Evaluation of Permax —This section reports event frequencies evaluated as of October 1988 for adverse events ocurring in a group of approximately 1,800 patients who took multiple doses of pergolide mesylate. The conditions and duration of exposure to pergolide mesylate varied greatly, involving well-controlled studies as well as experience in open and uncontrolled clinical settings. In the absence of appropriate controls in some of the studies, a causal relationship between these events and treatment with pergolide mesylate cannot be determined.

The following enumeration by organ system describes events in terms of their relative frequency of reporting in the data base. Events of major clinical importance are also described in the Warnings and Precautions sections.

The following definitions of frequency are used: frequent adverse events are defined as those occurring in at least 1/100 patients; infrequent adverse events are those occurring in 1/100 to 1/1,000 patients; rare events are those occurring in fewer than 1/1,000 patients.

Body as a Whole —*Frequent:* headache, asthenia, accidental injury, abdominal pain, chest pain, back pain, flu syndrome, neck pain, fever; *Infrequent:* facial edema, chills, enlarged abdomen, malaise, neoplasm, hernia, pelvic pain, sepsis, cellulitis, moniliasis, abscess, jaw pain, hypothermia; *Rare:* acute abdominal syndrome, LE syndrome.

Cardiovascular System —*Frequent:* postural hypotension, syncope, hypertension, palpitations, vasodilatations, congestive heart failure; *Infrequent:* myocardial infarction, tachycardia, heart arrest, abnormal electrocardiogram, angina pectoris, thrombophlebitis, bradycardia, ventricular extrasystoles, cerebrovascular accident, ventricular tachycardia, cerebral ischemia, atrial fibrillation, varicose vein, pulmonary embolus, AV block, shock; *Rare:* vasculitis, pulmonary hypertension, pericarditis, migraine, heart block, cerebral hemorrhage.

Digestive System —*Frequent:* nausea, vomiting, dyspepsia, diarrhea, constipation, dry mouth, dysphagia; *Infrequent:* flatulence, abnormal liver function tests, increased appetite, salivary gland enlargement, thirst, gastroenteritis, gastritis, periodontal abscess, intestinal obstruction, nausea and vomiting, gingivitis, esophagitis, cholelithiasis, tooth caries, hepatitis, stomach ulcer, melena, hepatomegaly, hematemesis, eructation; *Rare:* sialadenitis, peptic ulcer, pancreatitis, jaundice, glossitis, fecal incontinence, duodenitis, colitis, cholecystitis, aphthous stomatitis, esophageal ulcer.

Endocrine System —*Infrequent:* hypothyroidism, adenoma, diabetes mellitus, ADH inappropriate; *Rare:* endocrine disorder, thyroid adenoma.

Hemic and Lymphatic System —*Frequent:* anemia; *Infrequent:* leukopenia, lymphadenopathy, leukocytosis, thrombocytopenia, petechia, megaloblastic anemia, cyanosis; *Rare:* purpura, lymphocytosis, eosinophilia, thrombocythemia, acute lymphoblastic leukemia, polycythemia, splenomegaly.

Metabolic and Nutritional System —*Frequent:* peripheral edema, weight loss, weight gain; *Infrequent:* dehydration, hypokalemia, hypoglycemia, iron deficiency anemia, hyperglycemia, gout, hypercholesteremia; *Rare:* electrolyte imbalance, cachexia, acidosis, hyperuricemia.

Musculoskeletal System —*Frequent:* twitching, myalgia, arthralgia; *Infrequent:* bone pain, tenosynovitis, myositis, bone sarcoma, arthritis; *Rare:* osteoporosis, muscle atrophy, osteomyelitis.

Nervous System —*Frequent:* dyskinesia, dizziness, hallucinations, confusion, somnolence, insomnia, dystonia, paresthesia, depression, anxiety, tremor, akinesia, extrapyramidal syndrome, abnormal gait, abnormal dreams, incoordination, psychosis, personality disorder, nervousness, choreoathetosis, amnesia, paranoid reaction, abnormal thinking; *Infrequent:* akathisia, neuropathy, neuralgia, hypertonia, delusion, convulsion, libido increased, euphoria, emotional lability, libido decreased, vertigo, myoclonus, coma, apathy, paralysis, neurosis, hyperkinesia, ataxia, acute brain syndrome, torticollis, meningitis, manic reaction, hypokinesia, hostility, agitation, hypotonia; *Rare:* stupor, neuritis, intracranial hypertension, hemiplegia, facial paralysis, brain edema, myelitis, hallucinations and confusion after abrupt discontinuation.

Respiratory System —*Frequent:* rhinitis, dyspnea, pneumonia, pharyngitis, cough increased; *Infrequent:* epistaxis, hiccup, sinusitis, bronchitis, voice alteration, hemoptysis, asthma, lung edema, pleural effusion, laryngitis, emphysema, apnea, hyperventilation; *Rare:* pneumothorax, lung fibrosis, larynx edema, hypoxia, hypoventilation, hemothorax, carcinoma of lung.

Skin and Appendages System —*Frequent:* sweating, rash; *Infrequent:* skin discoloration, pruritus, acne, skin ulcer, alopecia, dry skin, skin carcinoma, seborrhea, hirsutism, herpes simplex, eczema, fungal dermatitis, herpes zoster; *Rare:* vesiculobullous rash, subcutaneous nodule, skin nodule, skin benign neoplasm, lichenoid dermatitis.

Special Senses System —*Frequent:* diplopia; *Infrequent:* otitis media, conjunctivitis, tinnitus, deafness, taste perversion, ear pain, eye pain, glaucoma, eye hemorrhage, photophobia, visual field defect; *Rare:* blindness, cataract, retinal detachment, retinal vascular disorder.

Urogenital System —*Frequent:* urinary tract infection, urinary frequency, urinary incontinence, hematuria, dysmenorrhea; *Infrequent:* dysuria, breast pain, menorrhagia, impotence, cystitis, urinary retention, abortion, vaginal hemorrhage, vaginitis, priapism, kidney calculus, fibrocystic breast, lactation, uterine hemorrhage, urolithiasis, salpingitis, pyuria, metrorrhagia, menopause, kidney failure, breast carcinoma, cervical carcinoma; *Rare:* amenorrhea, bladder carcinoma, breast engorgement, epididymitis, hypogonadism, leukorrhea, nephrosis, pyelonephritis, urethral pain, uricaciduria, withdrawal bleeding.

Letters to the Editor

Letters to the editor should be submitted as an original and two duplicates. They should be typewritten double-spaced on plain bond paper; they will be subject to editing. If they are prepared on a word processor, do not justify the right margin. A copyright transmittal letter signed by all authors must accompany this (see "Instructions for Authors").

Early Therapy for Parkinson's Disease

To the Editor.—We read with interest the article by Elizan et al in the January issue of the ARCHIVES.[1] The authors suggest that the early combination of selegiline and levodopa initiated at the "earliest clinical expression of the disease process" seems a most reasonable approach. They base this suggestion on their observation that patients receiving selegiline alone experience a dramatic improvement in parkinsonian score following the addition of levodopa (Sinemet). As selegiline alone provides little or no symptomatic benefit as monotherapy in early Parkinson's disease,[2] it is not surprising that a significant symptomatic response was observed with the addition of levodopa. As the authors point out, it is not known how the response to levodopa and selegiline compares with that which could be achieved with levodopa alone, a dopamine agonist alone, or the combination of selegiline and a dopamine agonist.

The rationale for the use of selegiline in patients with early Parkinson's disease is that it may slow disease progression by diminishing the accumulation of free radicals associated with the oxidative metabolism of dopamine.[2] However, selegiline does not completely prevent the oxidation of dopamine, which may also undergo auto-oxidation or metabolism by the monoamine oxidase type A inhibitor. Therefore, levodopa administration, by way of its metabolism to dopamine, may continue to promote free radical production despite concurrent selegiline therapy.[3] If oxidation reactions and free radical formation are important in the pathogenesis of Parkinson's disease, it may be best to minimize the cumulative dose of levodopa employed over the course of the disease. This can be accomplished by (1) using selegiline therapy to delay the need for the symptomatic therapy, (2) initiating symptomatic therapy with a dopamine agonist that does not undergo oxidative metabolism, and (3) administering levodopa as an adjunct when satisfactory symptomatic benefit cannot be obtained with selegiline and a dopamine agonist alone. The use of levodopa as part of combination therapy with a dopamine agonist and selegiline should permit clinical benefit to be obtained with a lower dose than if it were used alone. This strategy would provide symptomatic control while minimizing the cumulative levodopa dose and the potential for levodopa-induced oxidative stress. Prospective controlled clinical trials to evaluate this approach are necessary.

In Reply.—We thank Hauser and Olanow for their comments and appreciate the various therapeutic strategies that they propose and which have been detailed in a previous publication.[1] Since their suggestions rely heavily on the results of the DATATOP study,[2,3] a comment on its design and interpretation is in order. DATATOP was designed as a clinical trial to test the intriguing hypothesis (originally suggested by Birkmayer et al[4] in 1985) that long-term monoamine oxidase type B (MAO-B) inhibition with the drug, selegiline (L-deprenyl), will provide a "protective" effect on nigral degeneration and *slow* the progression of Parkinson's disease (PD). To date, this hypothesis remains *unproven.* The DATATOP results demonstrate an effect on the clinical status of treated patients compared with untreated control subjects receiving no active symptomatic treatment of any kind. The delay in the *need for levodopa* (the authors' end point) in the selegiline-treated patients compared with the untreated control subjects was interpreted by the authors as reflecting a delay in the underlying disease progression (hence, "protective" rather than "symptomatic"). The latter interpretation assumes that the observed effect of the drug has a fundamental *causal* relationship to the disease process, which may or may not, in fact, exist. Or, alternatively, the observed effect was interpreted as proving the hypothesis that generated it in the first place. Moreover, it was not clear that the design of the study as actually performed permitted a distinction between "symptomatic" and "protective" explanation for the need for levodopa.

We had elected to define clinical progression in de novo cases of Parkinson's disease[5] as the emergence of *new* signs and symptoms, and/or the demonstrable *worsening* of those previously present, after the start of selegiline monotherapy. We found that selegiline by itself failed to avoid either of these and that it had only a modest effect as primary symptomatic therapy in early PD.[5] As an adjunct to long-term levodopa therapy in the more advanced disease,[6] a beneficial symptomatic response in a selected group of patients was observed, but no effect on disease outcome. We have been more inclined to view these data as not supporting (although not necessarily disproving) the hypothesis that MAO-B inhibition and other therapeutic strategies directed at reducing oxidative stress will slow the progression of PD.

One cannot disagree with Hauser and Olanow's recommendation that it is desirable to limit the daily dose of levodopa. We have advocated this practice for years, but for reasons that are substantially different from those that they propose. Our concern is not the cumulative effect of levodopa contributing to neuronal degeneration but, rather, the development of erratic pharmacological effects that occur after long-term usage. In part, we feel that this may relate to usage of a large daily dosage of levodopa required for symptom control. Selegiline allows for reduction of such dosage.

We have long been acutely aware of levodopa's hypothesized potential role in the pathogenesis of the disease itself,[7,8] especially if oxidative reactions and free radical formation were, indeed, involved in nigral cell death of PD. But, in fact, there are no conclusive data supporting the idea that levodopa, particularly that derived from an exogenous source, induces cell death even in experimental systems,[9-11] and, certainly, there are no such data in human PD. After more than 20 years of levodopa use in clinical practice, there is no convincing evidence in the literature that levodopa induces neuronal degeneration or accelerates the progression of PD, even after long-term administration of the drug. We do not, therefore, share Hauser and Olanow's concern that levodopa will contribute to the progression of the parkinsonian process, although we agree with them that the cumulative dose over time be held to a minimum.

Our article suggests that the early combination of selegiline and low-dose levodopa is appropriate as *initial therapy* in PD. The sentence quoted by the authors where we recommend the use of this regimen "at the earliest clinical expression of the disease process" can be construed as calling for the use of levodopa as soon as the diagnosis of PD is made. This was not our intent. The decision to start definitive therapy is based on the judicious evaluation of the individual patient's unique need for symptomatic relief, however "early" that might be.

The remarkable symptomatic reversal of parkinsonism with the addition of low-dose levodopa in deteriorating patients on selegiline monotherapy for an average of 13.8 months,[12] dramatizes, not so much the well-known levodopa effect, but the *paucity* of effect ("symptomatic" or "protective") of selegiline alone. The trial of early combination of low-dose levodopa and selegiline as initial therapy that we reported[12] obviously needed to be compared, as we indicated, with low-dose levodopa alone or combined with a dopamine agonist to attempt to clarify the role of each drug. A manuscript in preparation ("Levodopa Revisited: Low-Dose Levodopa Alone or Combined Early With a Monoamine Oxidase Inhibitor, Selegiline: The First 4 Years") will address the question of whether or not the use of selegiline does make a difference in altering the clinical course of parkinsonism as well as avoiding some of the long-term complicated pharmacological responses of levodopa.

Trends in Parkinson's Disease Mortality in Italy

To the Editor.—In a recent issue of the Archives, Lilienfeld and colleagues[1] reported notable changes in age-specific mortality for Parkinson's disease (PD) during two decades (1962 through 1982) in the United States. The authors observed a decline in PD mortality rates among the middle aged and an increase in rates in the geriatric age group, both in whites and nonwhites and in both sexes. They concluded that these temporal changes, although possibly due to better case ascertainment and improved treatment of PD, may reflect a true rise in the incidence among the elderly, with some implication for the pathogenesis of the disease. Similar findings have been reported, but not discussed, by Li and colleagues[2] in England and Wales.

We have analyzed the mortality rates for PD in Italy in the period from 1957 through 1981 (*International Classification of Diseases* code 350.0 for the period from 1957 through 1966; 342.0 for the period from 1967 through 1978; and 332.0 for the period from 1979 through 1981). These data have been published yearly by the Italian Statistic Bureau, Rome. Only underlying causes are available.

The overall mortality rates, adjusted (for the 1971 Italian population), steadily increased during the period examined, both for men (1957 through 1961, 2.5/100 000 per year; for 1977 through 1981, 3.5/100 000 per year) and for women (1957 through 1961, 2.0/100 000 per year; for 1977-1981, 3.0/100 000 per year) (significance, $P < .001$). Furthermore, the following different trend was observed in the various age classes: the increase in mortality rates was evident among subjects older than 75 years of age, but a decrease was found among younger patients.

The cases were also analyzed by quinquennial birth cohorts: in both sexes, a progressive increase in mortality rates was found from the 1870 through 1874 cohort, with a maximum in the 1900 through 1904 cohort and a progressive decline in more recent cohorts. Interestingly, Brown and Knox[3] found a similar phenomenon in England and Wales during the period from 1943 through 1968, with a maximum in the 1895 through 1899 cohort. We feel that it is hard to ascribe these findings to methodological biases (such as better case ascertainment or modification in PD coding) or to the effect of new therapies that could cause delayed deaths (levodopa therapy was introduced in Italy in the early 1970s, while changes in mortality rates have been noted since 1960). On the contrary, these trends, observed in different geographical areas, seem to indicate that some cases of PD may have been caused by an environmental factor, possibly in the early decades of the 20th century, that had only a minimal or no effect after 1930. It would be useful to analyze the mortality rates reported in more recent years to confirm or deny the observed effect and also to analyze the variations in mortality in different geographical areas of the same country. Clearly, the definitive demonstration of this finding could give important support to the hypothesis that PD is caused by environmental or exogenous factors.

A Commentary on Steroid Treatment in Multiple Sclerosis

To the Editor.—A number of studies have shown that pulsed therapy with high-dose intravenously administered methylprednisolone is usually effective during multiple sclerosis (MS) relapses. It has been hypothesized that a regimen of repeated pulses of intravenous methylprednisolone, not restricted to relapses but given at regular intervals during the years of disease activity, might be effective in preventing progression of the disease. It can, however, reliably be predicted that under these circumstances the frequency of adverse effects will rise and, therefore, the importance of assessing the exact benefits and risks of such a regimen has been stressed in a number of leading articles.[1-3] We recently performed a small, open, pilot study in which monthly pulses of methylprednisolone (500 mg intravenously) were given to patients with progressive MS. Ten patients with definite MS according to the Poser criteria were selected for the study. During the 12 months before entry into the study all of the patients had deteriorated at least two steps (ie, one full point) on the Kurtzke Expanded Disability Status Scale (EDSS). The main aim of the study was to investigate the safety of this long-term steroid regimen.

Serum glucose and creatinine concentrations were examined monthly. Serum calcium, phosphate, alkaline phosphatase, osteocalcin, and parathyroid hormone concentrations, and the urinary calcium/creatinine and hydroxyproline/creatinine ratios were determined every 3 months to study bone metabolism. An increase of these urinary ratios would be indicative of increased bone resorption. Bone mineral densities were measured quantitatively in the lumbar vertebral column with dual energy X-ray absorptiometry and in the radius with single photon absorptiometry every 3 months. Guidelines for the clinical use of bone mass measurements have been given by Johnston et al.[4] Very recently, the importance of bone density measurements in MS trials involving steroid treatment was stressed by Whitham et al.[5] Cortisol response to corticotropin was tested every 3 months to examine adrenal function: cortisol levels were measured both before and 30 minutes after the intravenous administration of 0.25 mg of synthetic 1-24-corticotropin (Synacthen, Organon, Holland), and both relative and absolute increases were analyzed (short corticotropin stimulation test). To document the clinical course Kurtzke's EDSS was determined monthly.

After a mean treatment duration of 9 months there were no signs of cushingoid appearance, behavioral changes, or hypertension in any of the patients. Two patients had to be treated with antibiotics for lower urinary tract infections; no serious infections occurred. The treatment was tolerated well, although seven of 10 patients suffered from insomnia the night after the infusion. All laboratory parameters are given in the Table. It is clear that no clinically significant changes were found during the course of the treatment. There was no loss of bone mass (as documented by dual energy X-ray absorptiometry and single photon absorptiometry), there were no changes in bone metabolism (as documented by serum calcium, phosphate, alkaline phosphatase, osteocalcin, and parathyroid hormone concentrations and 24-hour urine calcium/creatinine and hydroxyproline/creatinine ratios), and there was no indication of any suppression of adrenal function (as documented by the short corticotropin stimulation test). The mean Kurtzke EDSS was 5.8 at entry and 5.5, 5.9, and 6.2 after 3, 6, and 9 months of treatment, respectively, resulting in a mean increase of 0.4 after 9 months (mean increase in the corresponding period before treatment 0.9).

Our data convincingly demonstrate that our treatment regimen (monthly infusions of 500 mg of methylprednisolone) can be administered in MS patients without side effects for at least 9 months. The findings on the complete absence of any change in bone mineral density measurements after this treatment duration are of special significance. It has previously been indicated that corticoid-induced loss of bone mass occurs predominantly within the first 5 to 7 months of treatment, whereas during the subsequent stages only minor changes can be observed.[6] Evaluating the same parameters as we did, several groups have demonstrated the occurrence of a bone loss of about 10% due to conventional oral dosing steroid regimens with cumulative dosage and treatment duration being comparable to ours (for review see Lukert and Raisz[7]). The absence of adrenal insufficiency in our patients is also remarkable since in other studies it was found that conventional regimens of prednisone with a cumulative dosage comparable to ours can lead to suppression of adrenal

Mean Laboratory Parameters Obtained Before and During the Treatment*

		Months		
	Before Entry	3	6	9
	Serum			
Glucose, mmol/L	4.8	5.0	4.6	4.1
Creatinine, µmol/L	82	84	84	82

function after only 2 to 3 weeks.[8,9]

Based on our findings, a large controlled study can be justified to evaluate the efficacy of this regimen of repeated pulses of intravenous methylprednisolone in the treatment of MS, either in the prevention of relapses or in preventing progression of the disease.

Epidural Steroids Are Safe and Effective When Given Appropriately

To the Editor.—We read with interest Nelson's[1] most recent attack on the use of intraspinal steroids. It appears that Nelson is continuing his relentless crusade to banish the use of epidural steroids, a crusade based, as usual, more on an emotional than on a scientific basis.

Initially it appears that the 19 references in his letter to the editor[1] would strongly support his viewpoint. However, on closer evaluation, one realizes that 14 of those 19 references are Nelson's articles, many of which are simply letters to the editor or lectures to others rehashing the same material.

The majority of the references discounting the use of intraspinal steroids address the intrathecal use. In addition, most of the complications encountered by Nelson, or quoted by him, occurred in patients with another significant neurologic disease process, ie, multiple sclerosis. And, when Nelson refers to Bernat's article[2] regarding a complication from intrathecal administration, he fails to mention the fact that this case was a subdural rather than subarachnoid injection, and he fails to refer to Bernat's later review article[3] when he emphasizes that the epidural route appears to be relatively safe.

It is significant to note that in Nelson's letter he refers to *60 Minutes Australia* and *A Current Affair Australia.* Although we are sure that these are interesting programs for public consumption, they would hardly qualify as reputable scientific references. He goes on to state that Upjohn altered its package insert in this country in 1989 to warn against epidural injections of Depo-Medrol, but on close examination of the most recent package insert, we can find no such warning.

Most anesthesiologists who administer epidural steroids agree that it is inadvisable to inject the steroid intrathecally, although even this is based more on medicolegal than on medical grounds. However, when administered appropriately, epidural steroid injections have an excellent safety record. In our clinic, Brooke Army Medical Center, Fort Sam Houston, Tex, we have administered over 5000 epidural steroid injections over the last 10 years without a single known case of arachnoiditis. Others[4-9] have reported a similar safety record.

Obviously, there are risks associated with any invasive procedure; and while complications are rare, Nelson has outlined those that have been reported very well. However, in medicine we must weigh the risks of any treatment against the benefits and compare that risk-benefit ratio with the alternatives; the alternatives to epidural steroids include bedrest, physical therapy, chronic drugadministration, and surgery, and in many instances these alternatives carry even a greater risk than epidural steroids and may, in addition, lead to further cost and loss of income.

Although we are unaware of how and to whom epidural steroids are administered in Australia, in this country we hear only a "ground swell" of patient appreciation for the relief obtained from our patients. When administered with proper expertise, with appropriate patient selection, with the proper dosage and when the injections are limited in number, we believe that the administration of epidural steroids will continue to be a safe and effective therapy for certain neurologic derangements. All of the above criteria are well outlined by Benzon[10] in his review article. We further believe that it is time for Nelson to stop beating a dead horse; if he continues and if we allow him to create the hysteria in the professional press similar to that generated in Australia in the lay press, we will only deprive our patients of a very important therapeutic modality.

In Reply.—Controversy concerning the intraspinal use of methylprednisolone acetate (Depo-Medrol, Upjohn Co, Kalamazoo, Mich) began in 1970, naturally leading to a number of editors' invitations (as here) for me to reply to adverse opinions.

The manufacturer issued its first warning concerning epidural use in the United States in October 1989 and in Australia in November 1990. Because the drug has a 36-month shelf life, Strong et al may not have yet seen the new package-insert pamphlet, and the

Upjohn Company plans no general "Dear Doctor" letter. Six months after the warning against epidural use in the United States was first printed, I was notified that about 150 patients in Western Australia claimed complications from epidural steroid therapy.[1] Why such a large number of patients in one Australian state spontaneously reported their symptoms without media induction or medical publications is unknown. Contrary to Strong et al, I believe that serious complications from *intrathecal* steroid therapy bear directly on potential dangers from *epidural* injections. Second, I believe that animal research has been inadequate. Two previous publications[1,2] summarized scientific conflicts attendant to intrathecal steroid therapy that began in 1960 and concerning epidural therapy that began around 1975. Thousands of intrathecal injections were given over the last 30 years in attempts to treat low back pain, disk disease, the failed back syndrome, as well as multiple sclerosis.[3-9] By far, the drug has been prescribed most frequently for nondescript back pain and sciatica, a 1960 regimen using methylprednisolone acetate, introduced by Sehgal and Gardner[6,7] and Sehgal et al.[8,9]

The steroid compound known to be neurotoxic contains approximately 30 mg of polyethylene glycol per milliliter.[10-13] Prior to human trials, Sehgal and colleagues[6-9] published no original animal research in which the above steroid compound was used, referring instead to works done by others who studied cortisone or hydrocortisone injected intrathecally. No subhuman primates have ever been tested. After numerous neurological complications were reported, the Upjohn Company issued their first warnings against intrathecal use in 1979 and 1980. Simultaneously, similar disturbing findings were published by three different groups of neuroradiologists[14-16] who together reported the occurrence of almost 100% arachnoiditis in 86 patients, even from a single small intrathecal dose of methylprednisolone acetate. Most neuroscientists thereafter abandoned its use, but anesthesiologists were already publishing that epidural therapy was safe and effective. An often quoted 1972 review article by Winnie et al[17] mentioned the safety of intraspinal steroid therapy by referencing the earlier work by Sehgal et al,[9] who—as explained above—apparently never did animal research using methylprednisolone acetate. Apparently relying on those previous reports, Winnie et al[17] (as did Sehgal and Gardner[6,7] and Sehgal et al[8,9]) only referred back to animal experiments done in 1955 by others who used cortisone and hydrocortisone—never methylprednisolone acetate.

In 1980, Delaney et al[18] reported that triamcinolone acetate, administered to only 10 cats, was safe when given epidurally. However, I note that animals given the vehicle alone demonstrated more meningeal changes. It was surprising to me that not until 1990 was methylprednisolone acetate finally tested on 12 rabbits by Cicala et al[19] who killed the animals on days 4 through 10 and reported no meningeal changes. This short-term research on such a minuscule series of small animals is inadequate to reassure human safety. Studies on large subhuman primates are obviously needed.

How often do epidural injections result in inadvertent spinal taps (thus virtually guaranteeing arachnoiditis)? Spinal fluid is obtained in 0.5% to 2.5% of routine epidural procedures.[20] Anesthesiology trainees have unsuccessful placements in 5%.[21] An experienced operator treating patients with spinal disease was unsuccessful in 6%.[22] Patients in pain clinics present technical problems to the operator because the "failed back" offers cicatricial obstructions to epidural catheters, resulting in inadvertent spinal taps. Even subdural placements can result in serious complications.

I respectfully request Strong et al to again read my last letter to the editor in the ARCHIVES[1] to which they object. Beginning at sentence 12, I described studies by Bernat et al[10] and Bernat[11] correctly when I wrote that a "second sac" was formed from an inadvertent subdural injection that spread intracranially. There will soon be a strong movement to abandon epidural therapy with methylprednisone acetate based on just published study by Johnson et al[23] from Australia. Following up on the original 1984 study by Roche[16] (in which he reported on radiographically proven arachnoiditis from intrathecal and epidural steroids), the new review disclosed that 20% went on to develop clinical signs and symptoms. Finally, the recent new edition of *Anesthesia*,[24] edited by Miller, summarized the present uncertain status of epidural steroid therapy by stating that such therapy is frequently ineffective for the "failed back" and by concluding, "Although this therapy is widely used and epidural administration seems relatively safe, use of steroids in a polyethylene glycol vehicle is probably not advisable."[24]

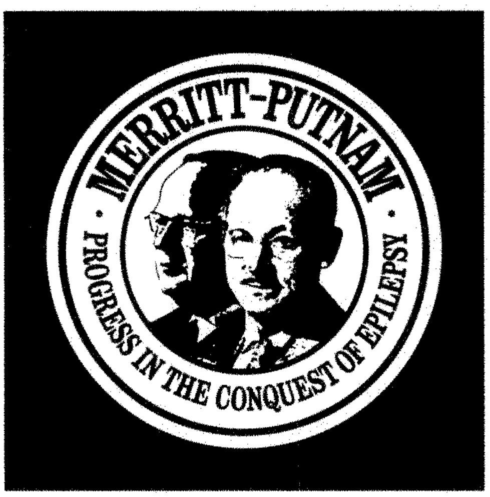
Parke-Davis is pleased to announce the Eleventh Annual Merritt-Putnam Symposium



MERRITT-PUTNAM
PROGRESS IN THE CONQUEST OF EPILEPSY

EPILEPSY THROUGH LIFE:

RECENT ADVANCES IN UNDERSTANDING AND TREATING EPILEPSY DURING PREGNANCY, CHILDHOOD, ADULTHOOD, AND OLD AGE

Saturday, December 7, 1991

8:30 AM – 4:00 PM
Wyndham Franklin
Plaza Hotel
Philadelphia, Pennsylvania

A Preeminent Educational Program for Neurologists and Other Healthcare Professionals Involved with Epilepsy Management

Sponsored jointly by the Department of Neurology, University of Minnesota Medical School; the American Epilepsy Society; and the Epilepsy Foundation of America, the 1991 Merritt-Putnam Symposium will explore current understanding about the treatment of the epileptic and special considerations of age in these individuals.

The outstanding faculty includes Ilo E. Leppik, MD, who also serves as chairman; Robert J. DeLorenzo, MD, PhD, MPH; Eli S. Goldensohn, MD; W. Allen Hauser, MD; Richard Lindhout, MD; Martha Morrell, MD; and W. Donald Shields, MD.

Category 1 CME credit will be offered by the University of Minnesota. For registration information, please call the Office of Continuing Medical Education at the University of Minnesota at (612) 626-5525.

The Merritt-Putnam Symposium is made possible through an educational grant from Parke-Davis, Division of Warner-Lambert Company.

Clinical Correlates of White-Matter Changes on Magnetic Resonance Imaging Scans of the Brain

Thomas R. Mirsen, MD; Donald H. Lee, DM; Cindy J. Wong, MSc;
J. Fernando Diaz, MD; Allan J. Fox, MD;
Vladimir C. Hachinski, MD, DSc(Med); Harold Merskey, DM

• We report our observations on the clinical and radiologic correlates of changes in cerebral white matter based on 94 subjects undergoing magnetic resonance imaging in a prospective study of dementia. Periventricular hyperintensity occurred twice as often in patients with Alzheimer's disease as in healthy control subjects. Within the control group, the presence of periventricular hyperintensity correlated significantly with one measure of cerebral atrophy and with the presence of changes in the adjoining deep white matter. The significance of white-matter changes distinct from the ventricles (leuko-araiosis) remains unsettled. Leuko-araiosis on the magnetic resonance imaging scan, unlike its correlate on the computed tomographic scan, was not shown to relate to cognitive decline or to the presence of focal abnormalities on neurologic examination. This is likely to reflect the heterogeneity of the changes detected with magnetic resonance imaging and their limited extent in our subjects.

(*Arch Neurol.* 1991;48:1015-1021)

Magnetic resonance imaging (MRI) permits the identification of subtle changes in the white matter of the brain.[1-3] Various investigators have reported a high prevalence of white-matter changes on T_2-weighted images,[1,2,4-10] especially in subjects with cerebrovascular disease.[1,2,4,5,7,8] We distinguish between periventricular hyperintensity (PVH) (Fig 1) and changes distant from the ventricles (Fig 2), or leuko-araiosis (L-A).[11]

SIGNIFICANCE OF L-A AND PVH

Leuko-araiosis appears infrequently on MRI scans[4,6,12] in young subjects and occurs more commonly[4,12] with age. It may appear often[5,12] and may be extensive[12] in Alzheimer's disease (AD).[5,12] However, our interpretation of the data of Erkinjuntti et al[13] suggests that severe changes are rare. Computed tomographic studies[14-16] reveal an association between similar lucencies and AD. No link exists between L-A on MRI scans and cognitive dysfunction, whether in AD,[12,13,17] among healthy control subjects,[18-20] in multi-infarct dementia (MID),[12] or in unselected subjects.[4] This contrasts with the relationship demonstrated between mental decline and L-A on CT scans.[21,22] Gait disturbance does relate to L-A on MRI scans of healthy subjects,[18] as previously shown for CT changes.[21] Leuko-araiosis appears on MRI scans in 64%[23] to 100%[12,13] of subjects with MID. Its effect on this condition remains unknown.

Periventricular hyperintensity is more prevalent than L-A in older[8-10,12] and possibly in younger[6,10,12] subjects. Its frequency casts doubt on its importance. The reported percentage of patients with AD who exhibit PVH varies from 44% to 100%.[12,13,17,23] One study[23] noted PVH in 71% of patients with MID, and other studies[12,13] noted PVH in 100% of patients with MID.

The incomplete knowledge regarding these white-matter changes results in part from variations among the existing studies.[*] Some rest primarily on preexisting radiologic data[7-10,35,41,45,47] or on pathologic findings.[†] The clinical information presented may be retrospective.[7-9,35,41] Given studies involve unselected subjects[1,4,7,10,41]; certain studies[5,17,26,29] involve modest numbers. Some investigators[5,6,20,32,33,43] report the prevalence of white-matter changes in various diagnostic groups; other investigators[‡] also delineate their extent. Most of these latter investigators[12,13,17-20,23,39,40,48] address the effect of these lesions on cognition. Many reports[12,13,18,20,39,40,48] include a neuropsychologic evaluation; some[17,23] rely on screening tools. Other studies[4,7-9,20,32,43,44] primarily examine the relationship between vascular risk factors and white-matter changes. Few[6,9,20,39,41] attend to focal neurologic findings. Other studies deal with the correlation between T_1[25,30,31] and T_2[26] measurements in the white matter and dementia.

No study has determined with certainty the contribution of white-matter changes seen on MRI scans to the severity of AD or MID. Bowen et al[12] stated that patients with AD exhibit more extensive L-A than do control subjects. However, Leys et al[17] found no effect of L-A or PVH on cognition in AD. Other studies[23,40] examined the effect of L-A and of PVH on cognition in cohorts of subjects with diverse diagnoses. Many studies have provided instructive infor-

mation, but it is difficult to control the numerous factors that influence the data.

Previous reports[15,21,22,38] from a large prospective study of dementia have examined the prevalence, clinical meaning, and probable cause of white-matter lucencies on CT scans. The acquisition of an MRI scanner and the presence of a pool of patients and control subjects who were examined systematically has made possible similar analyses based on MRI findings.

PATIENTS AND METHODS

The Dementia Study of the University of Western Ontario, London, which began in 1978, involves prospective clinical and radiologic examination of healthy volunteers and patients referred for the investigation of dementia. Participants in the study underwent standardized evaluation, performed from July 1985 to July 1986 by one physician (J.F.D.) and for the next 3 years by one neurologist (T.R.M.), confirmed in both cases by another neurologist (V.C.H.). Laboratory studies included a complete blood count; determinations of serum glucose, electrolyte, urea, creatinine, vitamin B_{12}, and folate levels; a liver profile; measurements of thyroid functions (including thyroid-stimulating hormone); and VDRL testing. Subjects initially underwent CT of the head. Magnetic resonance imaging scans have been obtained since November 1986, and electroencephalograms are obtained yearly. All testable subjects undergo psychometry at 6-month intervals, with the Extended Scale for Dementia (ESD),[49] with a sensitivity of 89% and a specificity of 96% in the identification of dementia.[50]

The physicians apply the *Diagnostic and Statistical Manual of Mental Disorders, Third Edition*, criteria[51] in diagnosis and use the Ischemic Score[52] to distinguish among AD, "mixed" dementia, and MID. Our diagnosis of AD has a sensitivity of 87% and a specificity of 78%.[53]

Magnetic resonance imaging scans were obtained with a 1.5-T unit (Signa, General Electric, Milwaukee, Wis). They were originally obtained as follows: in the sagittal plane, with a 24-cm field of view (FOV), a repetition time (TR) of 500 milliseconds and an echo time (TE) of 20 milliseconds, taking 5-mm sections 1 mm apart. Axial cuts involved a 20- to 24-cm FOV, a TR of 2000 milliseconds and TEs of 35 and 70 milliseconds, taking 5-mm sections with 2.5-mm gaps. Coronal cuts involved a 16-cm FOV, a TR of 2000 milliseconds, and TEs of 20, 40, 60, and 80 milliseconds, as well as a TR of 600 milliseconds and a TE of 20 milliseconds, taking 3-mm sections 3 mm apart.

Later, the sagittal TRs were changed to 400 milliseconds, and axial cuts were performed with a 20-cm FOV, a TR of 2500 milliseconds, and TEs of 30 and 70 milliseconds, with flow compensation and 5-mm contiguous sections. The coronal cuts involved a 20-cm FOV, a TR of 500 milliseconds, and a TE of 20 milliseconds, with a 5-mm section thickness.

Two neuroradiologists (A.J.F. and D.H.L.) independently analyzed the MRI scans obtained for the Dementia Study between November 1986 and May 1988, without knowledge of clinical diagnoses, for the presence of L-A, PVH, sulcal widening, ventricular dilatation, and infarction. Periventricular hyperintensity (Fig 1) refers to areas of heightened intensity at the margins of the lateral ventricles. We distinguish between PVH and L-A because some PVH may appear normally,[47] while L-A may represent infarction[24,27,28,46] or demyelination and gliosis.[24,28,42] Periventricular hyperintensity was classified as absent or present in each hemisphere separately; more elaborate classification proved unreliable because of discordance between observations made on coronal and axial sections. Most work has relied on axial views.[§] Where other cuts were taken,[1,5,12,19,39,41,48] assessments of severity apparently rested primarily on the axial cuts, although not in some instances.[12,39] We deemed small areas of hyperintensity at the frontal or occipital horns of the lateral ventricles as normal.[47] Leuko-araiosis was rated in each hemisphere according to the number and severity of lesions. Absence of lesions received a grade of 0, one or two focal lesions received a grade of 1, three to five lesions received a grade of 2, and more than five lesions received a grade of 3; confluent lesions received a grade of 4. Whether the changes were relatively superficial ("subcortical"), "deep" (within 2 mm of the ventricular border but separated by a strip of normal-appearing brain), or both was also noted. If the radiologists disagreed, they reviewed the appropriate film together. They agreed initially about the presence of L-A in 88% of cases, about its extent in 56% of cases, and about the site involved in 71% of cases; they agreed as to the presence of PVH in 76% of instances. These data refer to the right hemisphere; the left hemisphere yielded comparable results.

[§] References 6, 10, 13, 17, 18, 20, 32, 37, 40, 44, 47.

Sulcal widening, scored from 0 to 5 on a severity scale, was examined in five zones on either side: sylvian and retrosylvian areas, the high and low convexities, and the perimesencephalic cistern. The mean of all the values provided the sulcus widening score.

Ventricular dilatation likewise received a score between 0 and 5. It was assessed in two parts of the lateral ventricles—the temporal horns and the bodies together with the frontal horns—as well as in the third and fourth ventricles.

SUBJECTS AND METHODS

We reviewed information concerning 102 subjects from the Dementia Study who underwent MRI scanning between November 1986 and August 1988. Eight subjects were excluded because of doubt as to the presence or type of dementia. The remaining 94 subjects included 44 subjects suffering from dementia and 24 control subjects who underwent full investigation in the study within 2 years of MRI scanning. The remaining 26 subjects were control subjects examined before the introduction of a standardized neurologic evaluation form. However, their ESD scores remained in the normal range (>220) when they returned for MRI scanning.

We determined the prevalence of PVH and L-A, whether deep, subcortical, or both, and the severity of L-A in the various diagnostic groups (AD, mixed dementia, MID, and healthy control subjects). We assessed the relationship between PVH and age or sex among our subjects. We determined whether the presence of PVH or of either type of L-A bore a relation to the presence of atrophy, as measured by the sulcus widening score and by lateral ventricular enlargement. Lastly, we analyzed whether PVH and either variety of L-A appeared together. In all instances, the two hemispheres were assessed separately. All analyses, except for the last, were conducted with both the inclusion and exclusion of subjects with radiologically defined infarcts. Periventricular hyperintensity could not be assessed in three and L-A in two of the 94 scans because of poor image quality.

The effects of PVH and both types of L-A on the ESD score were assessed among 28 patients with AD and 39 control subjects independently. These were the persons with these diagnoses among the 81 of the original 94 subjects who had undergone psychometric evaluation within 6 months of MRI scanning. The radiologic findings were judged separately in each hemisphere.

To determine whether the presence of any focal neurologic finding correlated with the presence of PVH or of a type of L-A, we selected a further subset of 50 subjects. These subjects were those whose neurologic examinations were performed within 1 year of the MRI scanning. From these 50 subjects, we excluded four with MID, two with mixed dementia, and one with an uncertain diagnosis. This left 43 subjects remaining: 20 with AD, five with mixed dementia, and 18 healthy control subjects. The 43 subjects included those persons with mixed dementia according to the Ischemic Score but no evidence of cerebral infarction, as well as three AD patients and two control subjects with infarcts seen on the MRI scan. Exclusion of such persons would, by eliminating subjects with focal neurologic signs, reduce the chances of detecting an association between such signs and white-matter changes. We also kept the patients with mixed dementia in the analysis because they may have suffered from AD. Our diagnostic criteria maximize the purity of the AD group, so that some patients who prove to have AD on pathologic examination are classified clinically as having mixed dementia.[53]

The findings assessed appear in Table 1. Some were excluded from further consideration because they occurred in less than 5% of subjects. Most were compared with radiologic findings in the contralateral hemisphere, but some (dyspraxia, dysarthria, and primitive reflexes) were compared with findings on either side.

STATISTICAL ANALYSIS

Pearson correlation coefficients and χ^2 values were calculated as indicated between PVH or L-A and relevant variables. Fisher's Exact Test was used when cell sizes were small. The association between the severity of L-A and the presence of other characteristics, such as PVH, was examined with Kendall's τ statistic. The atrophy measures and the ESD score were compared with the Student t test. Partial correlations were computed to examine the prevalence of PVH in control and AD groups while controlling for age and sex. All P values are based on two-tailed tests.

RESULTS

The 94 study subjects included 30 patients with AD, nine with mixed dementia, and four with MID, 50 control subjects, and a man suspected to have encephalitis. The controls included 23 men and 27 women (mean [SD] age, 70.1 [9.7] years), six of whom exhibited small cerebral infarcts on the MRI scan. The demented subjects included 23 men and 21 women (mean [SD] age, 72.2 [7.8] years). The patients with AD included 13 men and 17 women (mean [SD] age, 72.8 [6.9] years), three of whom exhibited cerebral infarcts on the MRI scan. The subjects with mixed dementia included five men and four women (mean [SD] age, 70.7 [11.0] years). The patients with MID included four men (mean [SD] age, 69.9 [8.0] years).

Both PVH and L-A appeared to the same extent in the two hemispheres. Data are given only for the right side, except where a difference between hemispheres requires mention. On three scans, PVH could not be interpreted. Thus, it appeared in the right hemisphere in 18 (64%) of 28 patients with AD, in three of eight patients with mixed dementia, and in three of four patients with MID, as well as in 15 (30%) of the 50 control subjects. When subjects with infarcts seen on MRI scans were excluded, the prevalence for the right hemisphere in the AD group changed from 64% to 60% and in the controls from 30% to 31%. Whether subjects with infarcts are included or excluded, the difference in prevalence between the two groups is significant (χ^2, $P=.003$ and $P=.019$, respectively). This remains the case after controlling for age and sex ($P=.006$, if cases with infarcts are included; $P=.024$, if cases with infarcts are excluded). Examination of the prevalence of PVH in the left hemisphere, while controlling for age and sex, yields parallel results ($P=.019$, including cases with infarcts) and approaches statistical significance if cases with infarcts are excluded ($P=.066$).

Leuko-araiosis in the right hemisphere occurred in 27 (93%) of 29 patients with AD, in seven of eight patients with mixed dementia, and in all four patients with MID, as well as in 48 (96%) of the 50 control subjects. Leuko-araiosis could not be read on two scans. If subjects with cerebral infarcts were excluded, the prevalences in the AD and control groups changed little—to 92% and 96%, respectively. The severity of L-A does not correlate significantly with specific diagnoses; the data shown in Table 2 include subjects with radiologic infarcts. Exclusion of these subjects produces no significant change (data not shown).

Deep white-matter changes in the right hemisphere characterized 21 (72%) of the 29 patients with AD, six of eight patients with mixed dementia, and three of four patients with MID, as well as 28 (56%) of the 50 control subjects. If subjects with infarcts were excluded, the prevalence declined to 69% in the AD group and to 53% among the controls. No significant difference emerges between groups.

Subcortical L-A in the right hemisphere appeared in 25 (86%) of 29 patients with AD, in six of eight patients with mixed dementia, and in all four patients with MID, as well as in 47 (94%) of the 50 control subjects. Exclusion of subjects with infarcts yielded a prevalence of 85% in the AD group and of 93% in control subjects. The prevalence of subcortical L-A did not differ notably by diagnosis.

The presence of PVH in one hemisphere bears no link, neither in control subjects nor in patients with AD, to the presence of L-A as a whole or to the presence of subcortical L-A in the same hemisphere. Among control subjects, however, deep white-matter changes are associated with PVH (Table 3). A similar trend exists ($P = .194$) among patients with AD (Table 4). (Both Tables 3 and 4 refer to data from the right hemisphere.)

Control subjects with PVH display greater lateral ventricular dilatation (1.79 ± .99 [n = 14]) than do those without PVH (1.03 ± .69 [n = 31]) ($P = .005$). Patients with AD exhibit relatively more such dilatation than do controls, and patients with AD with PVH exhibit no more dilatation (1.93 ± .88 [n = 15]) than do those AD patients without PVH (2.00 ± .71 [n = 10]). These values represent lateral ventricular dilatation scores from the right hemisphere derived from subjects without cerebral infarcts and resemble scores from the left side. The mean sulcus widening score did not differ significantly between the cohorts with or without PVH, either in control subjects or in patients with AD.

Table 2.—Distribution of Leuko-araiosis (L-A) Scores by Diagnosis*

LA Score	AD	Control	Mixed Dementia	MID
0	2 (7)	2 (4)	1 (13)	0 (0)

Table 5.—ESD Score by Diagnosis*

	ESD Score		
Diagnosis	**Mean**	**SD**	**No. of Subjects**
AD	173.0†	53.5	28
Mixed dementia	179.8	79.9	9
Multi-infarct dementia	213.0	17.4	4
Other	178.0	. . .	1
Normal control	245.0	5.6	39

*ESD indicates Extended Scale for Dementia; AD, Alzheimer's disease.

†The mean ESD scores of the AD and control groups differ significantly ($P < .001$) (t test).

Neither in the control group nor in the AD group was there a link between L-A or either of its subcategories (deep and subcortical) and either of the two measures of atrophy (lateral ventricular dilatation and sulcus widening score).

Eighty-one subjects had ESD determinations within 6 months of MRI scanning (41 men and 40 women; mean [SD] age, 72.6 [6.9] years). They included 39 control subjects (20 men and 19 women; mean [SD] age, 73.2 [5.8] years) and 28 patients with AD (11 men and 17 women; mean [SD] age, 72.7 [7.0] years). The mean ESD scores for the diagnostic groups appear in Table 5. Subjects with infarcts seen on MRI scans were included. The mean values for the AD and control groups differed significantly, as expected. Exclusion of the three control subjects and two patients with AD with infarcts seen on MRI scans did not alter the results (data not shown).

Comparisons of the effect of the presence of PVH and of L-A—whether deep, subcortical, or both—on the mean ESD score failed to show any correlation within the AD or control groups. However, there existed a trend ($P = .097$, right hemisphere; $P = .176$, left hemisphere) for the ESD score to be lower among subjects with PVH than among those without it if control subjects and patients with AD were analyzed together. No link was found between any of the focal neurologic findings assessed and PVH, L-A, or either subcategory of L-A. This last analysis is based on a cohort of 17 men and 26 women, with a mean (SD) age of 67.5 (11.1) years.

COMMENT

Prevalence of White-Matter Changes

White-matter changes appear in 59% to 74%[18,19,44] of healthy aged subjects and in 80% of healthy middle-aged volunteers.[20] The prevalence of PVH on MRI scans likewise varies greatly. Bowen et al[12] identified PVH in 89% of 36 healthy subjects with a mean age of 70 years. Kertesz et al[8] found PVH "rims" in 98% of their 58 control subjects older than 50 years. Zimmerman et al[10] found PVH in 90% of studies with otherwise normal findings involving 63 subjects older than 30 years. The prevalence of PVH increases with age, but we find PVH in only 30% of our relatively old controls (mean age, 70 years). This may mean that changes that we denote as "deep" L-A are identified as PVH by other investigators. Also, we do not designate as PVH small triangular hyperintensities at the tips of the lateral ventricles, as other investigators may have done.

The prevalence of clinically silent changes in the white matter distant from the ventricles was reported to increase sixfold with age in one report[12] and fourfold in another report,[40] during a span of approximately 30 years; other investigators[6,29,39] have reported a similar trend. We found L-A in a similarly high percentage (96%) of control subjects. The higher prevalence of L-A and lower prevalence of PVH in our subjects compared with those of Bowen et al[12] suggests that they classify as PVH some changes that we consider to be L-A.

White-Matter Changes and Cognitive Function

Leuko-araiosis, as seen on CT scans, appears in 30%[14] to 33%[15] of patients with AD and in 10%[15] to 16%[14] of similarly aged control subjects. Other investigators[16] concur, finding relatively extensive lucencies in patients with AD. Kobari et al[43] observed L-A in 22% of young control subjects and in 62% of patients with AD, which is in agreement with findings of pathologic examination.[54] In contrast, Fazekas et al[33] found white-matter changes in 16% of controls and 13% of patients with AD. The presence of L-A correlates with decreased cognition[21] and may relate to psychomotor retardation[55] in healthy persons. Cognitive decline accompanies L-A in early AD.[22] Other studies[14,56,57] do not confirm this last observation, but our previous findings[58] support it strongly.

A weak relationship at best exists between the severity of dementia in AD and white-matter T_1[25] and T_2[26] values on MRI. Other investigators[30] have observed no association between T_1 values and cognitive decline in AD. Karlik et al[59] have suggested, based on only a few patients, that there is prolongation of T_1 in hippocampal white matter in AD.

Our findings regarding PVH establish the firmest link to date between AD and any type of change in white matter on MRI, although our neuropsychologic testing was not especially extensive. We found PVH twice as often in patients with AD compared with similarly aged control subjects (64% vs 30%), supporting the suggestion of Fazekas et al,[5] based on a smaller study, that PVH may accompany AD. Bowen et al[12] did not observe a difference in the prevalence of PVH between patients with AD and control subjects, although PVH was more widespread in the former group. Leys et al,[17] in a study based on few subjects, found a trend in this direction.

Information regarding L-A is less clear. It appears equally frequently in patients with AD and in control subjects (93% vs 96%) in our study group, as suggested by other authors.[5,6,17] Kobari et al[23] noted a tendency for L-A to appear more often, and to a greater degree, in patients with AD than in control subjects. Bowen et al[12] found a trend toward a higher prevalence of L-A in patients with AD compared with age-matched controls and a significantly greater severity of L-A in the former group. Their AD group included subjects with isolated memory disorders who did not meet criteria for dementia. These subjects displayed degrees of L-A and PVH comparable with those seen in AD. The increased involvement by PVH and L-A in that report may not, therefore, be specific for AD.

Other investigators[18,19] have stated that both L-A and mental decline in healthy aged subjects relate only to age rather than to one another. Rao et al,[20] in a study involving middle-aged subjects, reached similar conclusions. They stated the number and size range of L-A change in each subject, not an overall degree of white-matter involvement. Junque et al[39] found that L-A in subjects who are prone to cerebrovascular disease correlates with slowing of complex mental processing.

Leys et al,[17] in a study involving few subjects, reported no effect of PVH or L-A on mental function in AD. Cognitive impairment, as measured by the ESD, tends to correlate with the presence of PVH when patients with AD and control subjects are considered together, although not, as also noted by Bowen et al,[12] if the two groups are considered separately. The connection between PVH or L-A and mental impairment may bear further scrutiny, using either larger cohorts or using subjects with MID, who have more diffuse L-A.

MID

White-matter lucencies reportedly appear on CT scans in 52% to 97%[43,56,57] of patients with MID. These reports do not clearly differentiate L-A from PVH. The prevalence of L-A, based on our interpretation of the data, is between 20% and 30%.[56,57]

Small studies involving MRI[5,29] suggest that both PVH and L-A are especially extensive in MID. White-matter changes appear on MRI scans in eight of 11[40] and in all of 29[13] patients with MID, much more often than in AD[13] or in healthy subjects.[40] Periventricular hyperintensity most frequently occurs among controls but is most extensive in MID.[23] Other authors[12] have reported PVH universally in MID and AD alike, with greater severity in MID. Leuko-araiosis manifests in nine of 14[23] and in all of 12[12] patients with MID. It appears in four of nine[23] and in roughly two thirds of 87[12] patients with AD. The MID group exhibits more advanced changes.

Further investigations have assessed whether white-matter changes produce vascular dementia. Hershey et al[37] found PVH in 88% of patients with MID, a prevalence close to that seen in cognitively "borderline" (63%) and mentally intact (61%) stroke patients. Their patients with MID exhibited L-A four times as often (25% vs 6%) as did the mentally intact stroke subjects, but this finding was not statistically significant. A study of patients with lacunar infarction[48] revealed markedly more white-matter changes in demented subjects compared with "borderline" and cognitively unimpaired subjects. It remained unclear whether dementia related to L-A specifically or to lacunar infarction.

Loeb et al,[60] in contrast, found L-A more frequently among nondemented subjects with multiple strokes compared with patients with MID but did not examine its extent. Bowen et al[12] observed PVH and L-A alike in all subjects with memory complaints and Ischemic Scores in the MID range. Both changes were markedly more severe in this group than in other cohorts. Their presence did not influence the Mini-Mental Status Score.

To summarize the above, we found PVH in 75% of our patients with MID, in 38% of our patients with mixed dementia, and in 64% of our patients with AD. It occurred surprisingly infrequently in the mixed dementia group. The rather low prevalence in our MID and AD groups reflects our stringent criteria for PVH. The prevalence of L-A hovered near 90% in all of our diagnostic categories. Its severity did not differ significantly among the various groups. We found L-A in AD more often than in the roughly two thirds[12] or four tenths[17,23] of cases reported elsewhere. The low prevalence may stem from the exclusion of subjects with vascular risk factors.[17] In another instance, the authors[12] may, in comparison with our data, have underestimated L-A to the benefit of PVH.

We found, as did Bowen et al,[12] an association between L-A and MID. A demonstration that L-A contributes to intellectual decline in MID must await a large series of patients, with allowance made for the effect of stroke.

Focal Neurologic Signs and MRI White-Matter Changes

In the present report, we examined the relationship between focal signs on neurologic examination and MRI white-matter changes. Other such work, with two exceptions,[18,39] has focused on CT findings.

In a case-control study, Masdeu et al[61] identified an association between the severity of white-matter hypodensity and a history of falls. Rezek et al[16] observed a trend for motor abnormalities (abnormal tone, gait, or reflexes) to occur more frequently (67%) in patients with AD with L-A than in those without L-A (11%). No such relationship emerged among healthy control subjects. George et al[14] found gait disturbances substantially more often (45%) among demented subjects with L-A than among those without L-A (20%). Gait impairment was rare among elderly healthy subjects, regardless of the presence of L-A. George et al did not screen for other neurologic abnormalities. Steingart et al[21,22] observed, among both nondemented and demented subjects, that limb weakness and abnormal plantar responses correlated significantly with L-A. In healthy subjects,[21] gait difficulty and the rooting and palmomental reflexes also were related to L-A.

Previous studies have linked L-A, as seen on MRI scans, with gait impairment[18] and with primitive reflexes.[39] Both groups of investigators[18,39] screened only for certain focal neurologic signs. In one report,[18] the subjects were neurologically intact, which may explain why other correlations did not emerge. In the other study,[39] the presence of diverse cerebral insults may have masked an effect of L-A on focal deficits.

In patients with AD and in control subjects alike, we found that neither PVH nor L-A bears any relationship to focal neurologic signs. The absence of a correlation between L-A and either cognitive decline or focal findings supports the view[24] that L-A is a normal change in the aging brain. It clearly can reflect infarction,[27,28,42,46] however.

Periventricular hyperintensity is associated with AD and, in control subjects, with cerebral atrophy. A decrease in brain tissue may leave more free water to be resorbed at the ventricular border, yielding an increase in PVH.[10] Alternatively, PVH may result from increased transependymal seepage of ventricular fluid as a result of decreased brain hydrostatic pressure secondary to atrophy. No pathologic change, except increased water content, accompanies PVH,[34,36,47] although some investigators[24,25] dispute this.

Periventricular hyperintensity in AD does not correlate with atrophy. Patients with AD exhibit more lateral ventricular dilatation than do normal subjects with PVH. Its degree does not vary with the presence of PVH. As PVH is more common in AD than in normal subjects (64% vs 30%), its presence favors the former diagnosis. Among subjects without PVH, the presence of atrophy should suggest AD, although there is considerable overlap in the degree of atrophy exhibited by healthy subjects and patients with AD. Thus, either the presence of PVH or of atrophy without PVH may help to identify AD, while the absence of both entities may indicate normality.

In control subjects, PVH accompanies deep white-matter changes; a similar trend exists among patients with AD. The association of the two entities may reflect either a common pathogenesis, as they differ little in location, or difficulty in distinguishing between the two. Among control subjects, deep white-matter changes appear in the absence of PVH considerably more often than the converse (27% vs 4%; Table 3). This implies that deep white-matter changes herald the development of PVH in control subjects. Among patients with AD, similarly, deep white-matter changes without PVH appear slightly more often than does PVH without deep changes (20% vs 12%; Table 4). This may be explained in two ways: PVH and deep white-matter changes coexist, but neither produces the other; alternatively, the development of the latter may precede the appearance of the former, with this effect submerged in AD by a high prevalence of PVH from another cause.

The genesis of PVH in AD is unclear. White-matter changes seen on CT scans have been related to the presence of hypertension and of infarcts seen on CT scans[15] in a population of demented subjects. Rezek et al[16] found significantly elevated systolic blood pressures among patients with AD who exhibited white-matter changes compared with other patients with AD; some investigators[62] have observed the opposite trend. The absence of marked arteriolar changes in the white matter of some,[16,54,63] though not all,[14] patients with AD who exhibit white-matter lucencies has focused attention on other factors: cerebral amyloid angiopathy[38,64] and even hypotension.[54] The former involves meningeal vessels remote from the ventricle and likely produces L-A, not PVH. Increased water content or tissue loss in the white matter may generate PVH via the mechanisms postulated earlier. Increased water content appears in the white matter of patients with AD on autopsy.[54,63] One group[25,31] reported an increased T_1 value in the white matter of patients with AD relative to controls, but another group[30] did not. The presence or absence of PVH may help to diagnose or exclude AD, even though the cause of PVH itself remains uncertain.

Leuko-araiosis, as identified by MRI, embraces common and subtle changes of unclear cause. On microscopic examination,[24,27,28,42,45-47] some L-A represents areas of infarction, gliosis, or demyelination. It may also reflect other entities (etat crible, cysts, ventricular diverticulae, or venous angiomas) that spare the brain parenchyma and should not compromise neurologic function.

Although severe L-A can produce dementia,[65] its heterogeneity and often limited extent render assessment of its effects difficult. Prospective investigation involving more subjects and detailed neuropsychologic, neuroradiologic, and neurologic evaluations will resolve the issue. The effect of L-A may be more evident when it is more severe, as in MID; with MID, however, one must contend with the confounding effects of stroke. Leuko-araiosis may constitute a risk factor or marker for the development of mental decline, even if it produces no incapacity itself. Appropriate observation over time will yield the answer. Lastly, proper ascertainment of coexisting conditions will identify the causes of L-A and guide future treatment.

This work was supported by program grant 21 and grant MA 9125 entitled "Neuroimaging of Organic Dementia" from the Medical Research Council of Canada, Ottawa, which funded the MRI scanning, and by grants 66062889-44 and 66063768 from the National Health Research and Development Program, Department of Health and Welfare, Ottawa.

We thank all the members of the University of Western Ontario Dementia Study Group, especially Kim Wands, for their support and encouragement. We also thank Dalice Sim, PhD, for making available the resources of the Robarts Research Institute, and Lance Bailey for designing the database.

Improved Recognition of Leukoaraiosis and Cognitive Impairment in Alzheimer's Disease

J. Fernando Diaz, MD; Harold Merskey, DM; Vladimir C. Hachinski, MD;
Donald H. Lee, MD; Mary Boniferro, MEd; Cindy J. Wong, MSc;
Thomas R. Mirsen, MD; Hannah Fox, MBBS

• We identified 85 patients in a longitudinal study of dementia who had uncomplicated Alzheimer's disease and in whom computed tomography of the head and psychometric testing were conducted within a 6-month period following their entry into the study. Thirty-four patients (40%) had leukoaraiosis, which was disproportionately common in female patients (62% vs 15% in male patients). Analysis of covariance demonstrated a relative reduction of scores on the Extended Scale for Dementia in those patients who had leukoaraiosis, after adjusting for the confounding effects of age, sex, educational level, and duration of illness. Leukoaraiosis was also much more common in women, even after adjusting for the possible confounding effects of age, duration of illness, Extended Scale for Dementia score, and hypertension. Multiple regression analysis showed that leukoaraiosis accounted for 11.6% of the variance of the Extended Scale for Dementia scores. Leukoaraiosis, together with duration of illness, accounted for 18.2% of the variance. Leukoaraiosis is associated with a greater degree of cognitive impairment in patients with Alzheimer's disease.

(*Arch Neurol.* 1991;48:1022-1025)

Hypodensities of white matter on computed tomographic (CT) scans, described as leukoaraiosis (LA),[1] are more frequently associated with Alzheimer's disease (AD) than with normal aging.[2-6] However, the relationship between LA and the degree of cognitive impairment in subjects with AD remains unsettled. Contradictory results from previous studies[2,5,7,8] may be due to differences in the populations sampled, the criteria for both AD and LA, or the sensitivity of various psychometric tests of intellectual impairment. The sensitivity of the scanner and the experience of the radiologist may also be relevant.

Furthermore, the relationship between LA and cognitive impairment may be confounded by a number of variables. Age,[4,5,9-11] stroke, hypertension,[10,12-17] and severity of AD[4,5,7] are all related to LA. Perhaps duration of illness could also affect the occurrence of LA. Cognitive ability decreases with age,[18] stroke,[19] hypertension,[20] and the duration and severity of AD. Formal education may confound the relationship because it influences psychometric test performance.[18] However, these effects may not fully explain the association between LA and intellectual impairment.[4,5]

In the present study, we compared patients with AD with LA and without LA in terms of the degree of cognitive impairment, taking into consideration potential confounding effects of other variables.

PATIENTS AND METHODS

The patients were selected from the University of Western Ontario (London) Dementia Study, a longitudinal research project described elsewhere.[21,22] They included all the patients clinically diagnosed as having AD according to the *Diagnostic and Statistical Manual of Mental Disorders, Third Edition Revised*, criteria[23] who had undergone CT scanning of the head and psychometric testing completed within a 6-month period following their entry into the study. A history of stroke, cerebral infarcts as seen on CT scans, and a primary neuropathologic diagnosis other than AD made post mortem were used as exclusion criteria to maximize the diagnostic accuracy of AD. Forty-five patients had died, and the diagnosis of AD was confirmed in 25 patients during autopsy. In the other 20 patients, postmortem examination was not performed.

The study sample included 59 patients from the group of patients discussed in a previous study[5] who satisfied the above criteria as well as an additional 26 new cases. Our study differed from the previous one[5] in that all CT scans were newly interpreted, and additional variables were analyzed.

The clinical diagnosis was established by a research fellow in neurology (T.R.M. or J.F.D.) and reviewed by one of us (V.C.H.). It was based on a systematic comprehensive evaluation.[21,22] When compared with the postmortem neuropathologic diagnosis in a subsample of patients, the clinical diagnosis of AD showed an overall accuracy of 83.1%, a sensitivity of 86.8%, and a specificity of 77.8%.[22]

CT Study

Two different CT scanners were used. Subjects who entered the study before October 1986 underwent scanning with a GE 8800 model scanner (General Electric, Milwaukee, Wis); the remainder underwent scanning with an updated GE 9800 model (General Electric). Both scanners were set for a 10-mm section thickness; 5-mm contiguous sections were obtained through the temporal lobes. No contrast material was used.

Compared with the GE 8800 scanner, the GE 9800 model reduces beam-hardening ar-

tifact and shortens the scanning time (2.4 seconds vs 2.8 seconds), which reduces the effects of patient motion and improves resolution (0.35 to 0.45 mm vs 0.75 mm). The new scanner also features an increase in the scanning aperture and in the amount of maximum gantry tilt. As a result, lesions were better visualized with the updated GE 9800 scanner.

A neuroradiologist (D.H.L.) interpreted all the CT scans in a "blinded" manner. The presence of LA and infarcts was established on the basis of specific criteria.[24] Moderate to substantial interobserver agreement has been shown in a subsample of CT scans, as reflected by mean pairwise κ values of .67 for LA and .57 for infarcts.[4]

Leukoaraiosis was categorized as focal when two or fewer areas of ill-defined hypodensity were seen in a hemisphere and as diffuse when more than two areas of hypodensity or confluent hypodensity were seen in a hemisphere.

Psychometric Testing

Cognitive impairment was graded by the Extended Scale for Dementia (ESD),[25] which was developed as a revision of the Mattis Dementia Scale.[26] The total ESD score is derived from 23 weighted subscores and has a maximum of 250 points. The lower the score, the more profound the cognitive impairment. Two psychometrists completed all the ESD measurements without knowledge of the CT findings.

The ESD demonstrates mild to severe degrees of cognitive decline with high test-retest reliability ($r=.94$) and internal consistency (Kuder-Richardson 20 coefficient of .943).[25] With a cutoff point of 221, the ESD discriminated demented from nondemented elderly subjects with an overall accuracy of 94%.[27]

Variables

The sociodemographic characteristics under study included age, sex, the highest level of formal education attained, and occupation. Social class was graded on a scale for Canadian occupations.[28] The other variables included the duration of dementia (as elicited from the next of kin), the ischemia score,[29] the electroencephalographic grade of abnormality,[30] hypertension, blood pressure values, and ESD score. On the CT scan, the presence or absence of LA and its type (diffuse or focal) were noted.

Hypertension was defined as the presence of one or more of the following: (1) a systolic blood pressure greater than 160 mm Hg, (2) a diastolic blood pressure greater than 90 mm Hg, and (3) a previous medical diagnosis of hypertension. The blood pressure values were recorded from the right arm while the subject was seated.

Statistical Analyses

Univariate analyses, with use of the χ^2 test for dichotomous or categorical variables and the Pearson correlation coefficients and two-tailed t-tests for continuous variables, were performed to assess the relationships among the study variables. Analysis of covariance and multiple regression analysis were used to explore the association between LA and ESD scores while simultaneously controlling for confounding effects from other variables. Multiple logistic regression was used to examine the effect of sex on LA while adjusting for other potential confounders. The analyses were performed with the SPSSX[31] and the SAS.[32]

RESULTS

The 85 patients had a mean (±SD) age of 70.8±8.4 years. Forty-five patients (52.9%) were female, and 83 (98%), including all of those with LA, had an ischemia score[29] of 4 or lower, which supported the diagnosis of AD. The ischemia score was missing in one patient, but AD was diagnosed during the postmortem examination. One patient without LA had an ischemia score of 5, but the course of his illness and the absence of infarcts on CT scans supported the clinical diagnosis of AD.

Leukoaraiosis was present in 34 (40%) of the patients. Diffuse LA was identified in 10 cases (12%) and focal LA in 24 (28%). Forty percent of the patients had had hypertension. The mean duration of the illness to the time of CT scanning was 4.1±2.6 years, with a median of 3.4 years. The mean duration for those with onset before the age of 65 years compared with those with onset after the age of 65 showed only a small difference that did not suggest earlier diagnosis of those still employed (onset before age 65 years, 4.7±3.14 years; onset after age 65 years, 3.91±2.25 years).

The mean ESD score was 132.1±80.8, with a range of 0 to 237. The intellectual impairment was considered mild (ESD score greater than 189) in 35.3% of the patients, moderate (ESD score, 70 to 189) in 36.5% of patients, severe (ESD score, 21 to 69) in 10.6% of patients, and advanced (ESD score, 0 to 20) in 17.6% of patients. The new scanner was used in only nine cases, identifying LA in three cases. The old scanner was used in the remaining 76 cases, showing LA in 41% (Fisher's Exact Test [two-tailed], $P=.74$). Information was lacking concerning the educational level of six patients. Only 4% of the patients for whom this information was available had not attended school. Forty percent had attended elementary school or some high school, and 56% had completed high school or attended a college or university.

Table 1.—Clinical Characteristics of the Patients With and Without Leukoaraiosis*

	Leukoaraiosis	
Variable	Absent (n = 51)	Present (n = 34)
ESD score	154.4 (75.3)†	98.6 (78.1)†
Duration of dementia, y	3.8 (2.0)	4.6 (3.3)
EEG		
Normal	15.5	13.3
Mild abnormality	37.8	20.0
Moderate abnormality	28.9	30.0
Severe abnormality	17.8	36.7
Hypertension	31.4	38.2
Systolic blood pressure, mm Hg	138.5 (20.5)	140.0 (19.7)
Diastolic blood pressure, mm Hg	78.9 (10.2)	76.7 (9.5)

*Values are mean (SD) or percent. ESD indicates Extended Scale for Dementia; EEG, electroencephalogram.

†$P < .001$.

Table 2.—Sociodemographic Variables of Patients With and Without Leukoaraiosis*

	Leukoaraiosis		
Variable	Absent (n = 51)	Present (n = 34)	P
Age, y	68.0 (8.6)	75.1 (6.0)	.0001
Sex			
M (n = 40)	85.0	15.0	.0001
F (n = 45)	37.8	62.2	
Education			
≤Grade 11 (n = 35)†	62.9	37.1	.5
Grade 12+ (n = 44)†	56.8	43.2	

*Values are mean (SD) or percent.

†Information on education was not available for six patients.

Tables 1 and 2 compare the clinical and sociodemographic characteristics of the subjects in terms of LA. Cognitive impairment was more pronounced in the group with LA compared with the group without LA. A 56-point mean difference in the ESD score was both clinically and statistically significant. However, no significant difference in the ESD score emerged between patients with diffuse and focal LA who scored 107±76.8 vs 95±80.0, respectively ($P=.7$). Except for the categories of "counting backward" and "counting by threes," all 23 mean ESD subscores were significantly lower in the group with LA ($P<.05$).

A higher degree of electroencephalographic abnormalities, reflecting more severe disease, in those patients exhibiting LA is consistent with their lower ESD score.[28] The more pronounced cognitive deterioration of the patients with LA could not be explained by longer duration of their AD. However, those with LA were significantly older ($P<.0001$) and predominantly female ($P<.0001$). No significant differences were found for education, social class, and blood pressure values. The effect of sex on LA was examined further by logistic regression analysis, including sex, age, duration of illness, hypertension, and ESD score as predictor variables for LA. The effect of sex on LA remained significant ($P<.0003$) after adjusting for the other sigificant confounding variables (age and ESD score), the odds ratio for the occurrence of LA in female patients being 9.96.

As expected, the ESD score was inversely correlated with age ($r = -.13$, $P = .22$) and duration of AD ($r = -.31$, $P = .004$). Female patients showed a significantly lower mean ESD score than did male patients (116 ± 78.8 vs 150 ± 76.5; $P = .05$). Patients with grade 11 and lower educational levels showed a lower mean ESD score (126 ± 74.2) compared with those with a higher educational level (140 ± 83.0), but the difference did not reach statistical significance. No significant associations emerged between ESD score and hypertension or blood pressure values.

In summary, the univariate analysis showed an association between LA and lower ESD scores and suggested potential confounding effects from age, sex, duration of AD, and educational level. Therefore, a multivariate analysis was performed to control for these effects.

Examination of the ESD score as a function of LA, age, sex, and duration of illness with analysis of covariance revealed significant effects from LA ($P = .01$) and duration of illness ($P = .02$) but no significant effects from age ($P = .52$) or sex ($P = .87$). A simplified model, including only LA and duration of the dementia, showed significant effects from both variables ($P = .003$ and $P = .01$, respectively).

Multiple regression analysis showed that LA alone accounted for 11.6% of the variation in ESD scores, while LA and duration together accounted for 18.2%. Adding age and sex to the model increased the explained variation of the ESD scores by only 0.37%. Therefore, among the variables introduced in the model, only LA and duration of illness were significantly associated with cognitive impairment. However, LA alone explains only approximately one tenth of the variation in cognitive impairment observed in patients with AD.

COMMENT

Our study results show that the presence of LA is associated with increased cognitive impairment in AD after taking into consideration the confounding effects of age, sex, duration of illness, and the level of formal education. However, LA accounts for only a small proportion of the variation in cognitive impairment, suggesting that other factors associated with the degenerative process of AD may account for most of the cognitive deterioration seen in AD.

An association between the severity of LA and the severity of AD was reported by George et al[2] but was not confirmed by Erkinjuntti et al.[7] Rezek et al[38] showed a relationship between the extent of LA and intellectual decline. Findings of a longitudinal study[8] showed that patients with early AD experienced the same intellectual decline, regardless of the presence or absence of LA. However, previous data from our group[5] showed that LA accompanied lower scores on the ESD only in the less advanced cases of AD. Magnetic resonance imaging studies have also yielded contradictory findings,[17,34-36] which are discussed in another report by our group (T.R.M., D.H.L., C.J.W., et al, unpublished data, 1990). Discrepant results from CT and magnetic resonance imaging studies may be due to differences in the study samples, criteria for both AD and LA, the potential of the psychometric tests to measure various degrees of intellectual impairment, and the sensitivity of the scanner to detect LA.

Previously published CT studies have reported a frequency of LA with AD ranging from 13%[37] to 19.7%[7] to 30%.[2] Our group previously reported a frequency of 33%[16] in patients, many of whom were included in the current study. The differences appear to be due to methodologic variations from other studies and to improved recognition of LA with experience. The predominance of LA in women in our study after allowing for possible confounding variables is unexplained. We previously reported increased LA in men,[16] but that study also included patients with overt vascular disease. The present report deals with a group that, to our knowledge, has only AD.

The improvements in our study are the increased accuracy in the detection of LA, the use of analyses to control for the confounding effects from other variables, and the inclusion of patients with a wide degree of impairment. As in the past,[22] we have supported the diagnosis of AD in our patients by continued clinical follow-up, neuropathologic data, and the exclusion of patients with stroke and infarcts as seen on CT scans.

The cross-sectional design of this study does not permit conclusions to be drawn regarding causality. Therefore, the present results showing a clear association between LA and the degree of intellectual decline support the need for a longitudinal study to clarify the question of whether LA contributes to the intellectual deterioration observed in AD.

This work was supported by program grant 21 from the Medical Research Council of Canada, Ottawa, and by grants 66062889-44 and 66063768 from the National Health Research and Development Program, Department of Health and Welfare, Ottawa.

We thank all the members of the University of Western Ontario Dementia Study Group, especially Kim Wands, for their support and encouragement. Lucy Carriere, MA, performed some of the psychometric tests. We thank Dalice Sim, PhD, for making available the resources of the Robarts Research Institute, London, Ontario.

Cerebrovascular Instability in a Subset of Patients With Stroke and Transient Ischemic Attack

Lars Friberg, MD, Tom Skyhøj Olsen, MD

• In six patients, we observed remarkably unsteady blood flow and indications of vasospasms on the arteriolar level in connection with episodes of focal cerebral ischemia. The patients originated from a prospective consecutive study of 53 patients with stroke and transient ischemic attack who had been examined by cerebral angiography and rapidly repeated regional cerebral blood flow measurements using the intracarotid xenon 133 method. In 47 patients, regional cerebral blood flow values, flow patterns, and clinical condition were stable during the repeated regional cerebral blood flow measurements. In six patients, pronounced regional hypoperfusion and hyperperfusion developed during the course of examination. In the hypoperfused regions, flow was transiently reduced to values consistent with ischemia, and in four of these patients this was accompanied by transient neurological deficits. The arteriogram and isotope angiograms ruled out spasms of large arteries or thromboembolism. A condition of cerebrovascular instability on the arteriolar level probably was induced by the examination procedure. These patients were hypersensitive to the provoking stimuli either habitually or as a consequence of previous ischemic accidents. It is suggested that in some patients with focal cerebral ischemia, the primary cause might be spasms of the smallest resistance vessels rather than thromboembolism.

(*Arch Neurol.* 1991;48:1026-1031)

A major part of focal cerebral accidents are due to thromboembolism. Arterial spasms have been considered another possible cause of focal cerebral ischemia. However, with the exception of cases of subarachnoid hemorrhage, arterial spasms have only rarely been demonstrated on cerebral angiograms. Consequently, vasospasms generally have been rejected as a possible pathophysiological mechanism of focal cerebral ischemia in patients with transient ischemic attack (TIA) and stroke. In this article, we present evidence that vasospasms in fact might be a cause of focal cerebral ischemia in some patients suffering from TIA and stroke. However, these spasms occur on the level of the smallest cerebral resistance vessels and are therefore not visible on a cerebral angiogram. We focus on the description of six patients from a consecutive study of 53 patients with recent cerebral ischemic events. During measurements of regional cerebral blood flow (rCBF), we found a remarkably unsteady regional perfusion of the cerebral cortex, suggesting instability of the cerebrovascular tone. In these six patients, we failed to demonstrate embolic sources, and there were no spasms of the vessels visible on the angiogram. In five patients, there were no angiographic signs of vascular occlusions.

PATIENTS AND METHODS

Patients

This report describes the investigation of six patients from a group of 53 who were examined consecutively in a prospective study. They were admitted to the hospital in direct connection with the appearance of neurological symptoms suggesting acute ischemic cerebral accidents. Patients with severe, disabling diseases or advanced malignant diseases were not included in the study. Excluded from this study were patients with brain-stem and cerebellar lesions, intracerebral hematomas, or myocardial infarction within 3 months of TIA or stroke. Also excluded were patients in whom the angiography revealed occlusion or tight stenosis of the internal carotid artery that made it impossible to measure rCBF with the intracarotid method.

Thirty-two men and 21 women were included (mean age, 64 years; range, 44 to 75 years). The six patients described in detail in this report were two men and four women (mean age, 66 years; range, 61 to 73 years) (Table 1). The protocol was approved by the Medical Faculty of the University of Copenhagen, Denmark.

Methods

All patients underwent the same examination procedures, including a full clinical neurological examination at the time of arrival to the hospital. Clinical examinations were repeated several times during the ward period. Cerebral angiography and rCBF measurements were performed within 12 to 24 hours after admission and in no case later than 48 hours after debut of the symptoms. A computed tomographic scan was carried out 1 day later and repeated after approximately 2 weeks and 6 months. The patients were examined for atrial fibrillation and previous myocardial infarction. Electrocardiography was performed in all.

Cerebral Angiography.—Puncture of the relevant common carotid artery was done using local anesthesia, and angiography of the carotid system and cerebral vessels was performed by administering the contrast medium through the cannula. The angiograms were inspected immediately. By the Seldinger technique, we introduced a small, soft, polyethylene catheter into the internal carotid artery after cerebral angiography.

rCBF Measurements.—Immediately after the cerebral angiography, we measured rCBF with the intracarotid xenon 133 injection technique.[1] Two hundred to 400 MBq of ^{133}Xe dissolved in 3 mL of saline was injected through the catheter, and for the following 2 minutes the clearance of isotope was recorded with a 254-detector gamma camera covering one hemisphere.[2] Each detector recorded radiation from approximately 1 cm^2 of the brain surface. Immediately after the isotope injection, each detector recorded the count rate with 1-second sampling intervals. The fast passage of high isotope concentrations through the carotid siphon and the middle and anterior cerebral arteries could be identified as vascular spikes in the clearance curve obtained with detectors covering these large vessels.[3] In the normal brain, vascular spikes occur within 1 to 3 seconds, and subsequently the isotope (blood) is distributed throughout the brain cortex. Here the maximum count rate plateau is obtained within

2 to 4 seconds after the bolus injection. Thus, the early isotope distribution and count rates can be used in evaluating the arterial distribution of blood.

For each detector, CBF (measured in milliliters per 100 g per minute) was calculated as the initial slope of the logarithmically transformed ^{133}Xe clearance curve obtained from 12 to 60 seconds after the bolus injection[4]: $CBF = k \times \lambda \times 100$, where k is the rate constant and λ is the tissue-to-blood partition coefficient for ^{133}Xe, which is 0.87 mL/g in gray matter. All data were automatically corrected for background activity and for clearance of the small amount of remaining isotope, which could be present when rCBF measurements were carried out with short intervals. There was a time interval of 15 to 20 minutes between the first and second measurements, and the following measurements were done with approximately 10-minute intervals. After computation, the data were visualized as a two-dimensional color picture of the lateral aspect of the brain (Fig 1), and the calculated values could be obtained from a printer (Fig 2). After the rCBF study, we examined the 254 clearance curves from each measurement. Simultaneously with each rCBF measurement, PCO_2, mean arterial blood pressure, and heart rate were recorded via the intracarotid catheter. The flow values were not corrected for PCO_2 changes in this study.

All repeated measurements were performed during a resting condition. Abnormal rCBF in a region was defined by the following criteria. A region should consist of at least 10 adjacent detectors representing approximately 10 cm^2 of the cortical surface. In the normal brain, the SD of the difference between repeated rCBF measurements in a 10-detector region is 3.3%.[5] We have chosen to define a hypoperfused region as 10 neighboring detectors each having at least a 20% lower rCBF value than found during the measurement when there were no symptoms and the rCBF pattern was evaluated to be normal. Therefore, mean rCBF in a hypoperfused region was at least five times beyond the expected SD in normal subjects. A hyperperfused region was defined as at least 10 adjacent detectors each recording rCBF increases of more than 40%. In this way, we minimized the risk that the focal blood flow increase was due to physiological activation, as 40% is more than twice the SD of the average focal activation response seen during pure intrinsic mental activity.[5]

RESULTS

rCBF Patterns and Angiography

When analyzing serial aspects of the rCBF patterns, we found a remarkably unsteady flow distribution in six patients. These rCBF patterns differed significantly from those of the remaining 47 patients. Therefore, the patients were considered belonging to two different groups, which we henceforth will refer to as groups 1 and 2.

Group 1.—In 47 patients, the rCBF patterns showed unaltered blood flow distribution during repeated measurements. If a region of focal hypoperfusion or hyperperfusion was present, this abnormality was found during all measurements. That is, the rCBF values and the localization and extension of the abnormally perfused regions were the same during all measurements. In this group, there was angiographic evidence of occlusions of the middle cerebral artery or peripheral branches from this artery in 23 patients. The angiography did not reveal signs of arterial occlusions or arterial spasms in 24 patients.

Group 2.—In six patients, the sequential rCBF measurements were completely different from those of group 1. In these six patients, the flow distribution was remarkably unsteady. During the examination, foci of hyperperfusion and hypoperfusion developed in different regions of the examined hemisphere. The calculated rCBF values and the extension of these abnormally perfused regions altered from measurement to measurement. They increased or decreased in size, and low or high mean blood flow was more or less pronounced. In case 2, it was only possible to carry out one measurement, as the patient felt great discomfort owing to the appearance of a new TIA. This patient was included in group 2 because a clearly abnormal rCBF pattern was associated with the appearance of neurological deficits and because the retrospective analysis of the clearance curves revealed that these were remarkably unstable. Figure 1 shows the changing rCBF patterns, and Fig 2 illustrates the localization and extension of the hyperperfused and hypoperfused regions. The global mean CBF is indicated in Table 2, and mean blood flow values in the affected regions are indicated in Table 3.

In five patients, the angiograms were

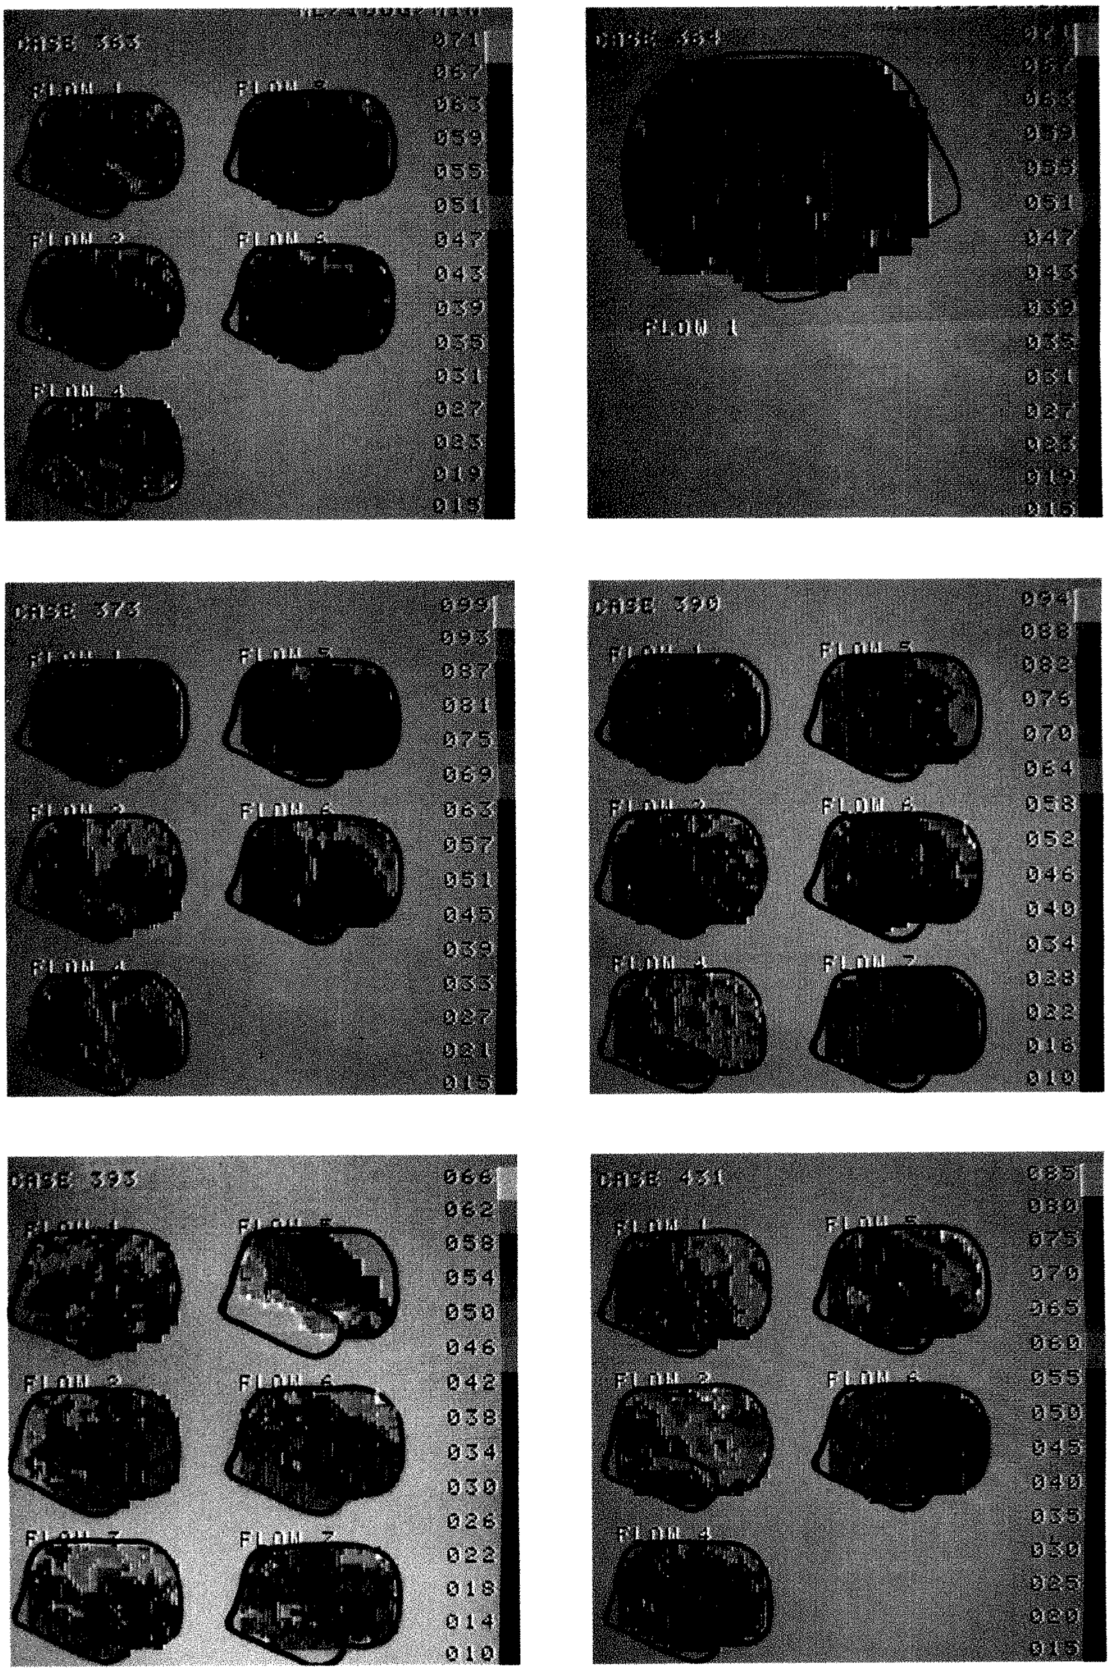

Fig 1.—Regional cerebral blood flow patterns from individual measurements. Color scale indicates blood flow in milliliters per 100 g per minute. Top left, Case 1; top right, case 2; center left, case 3; center right, case 4; bottom left, case 5; and bottom right, case 6.

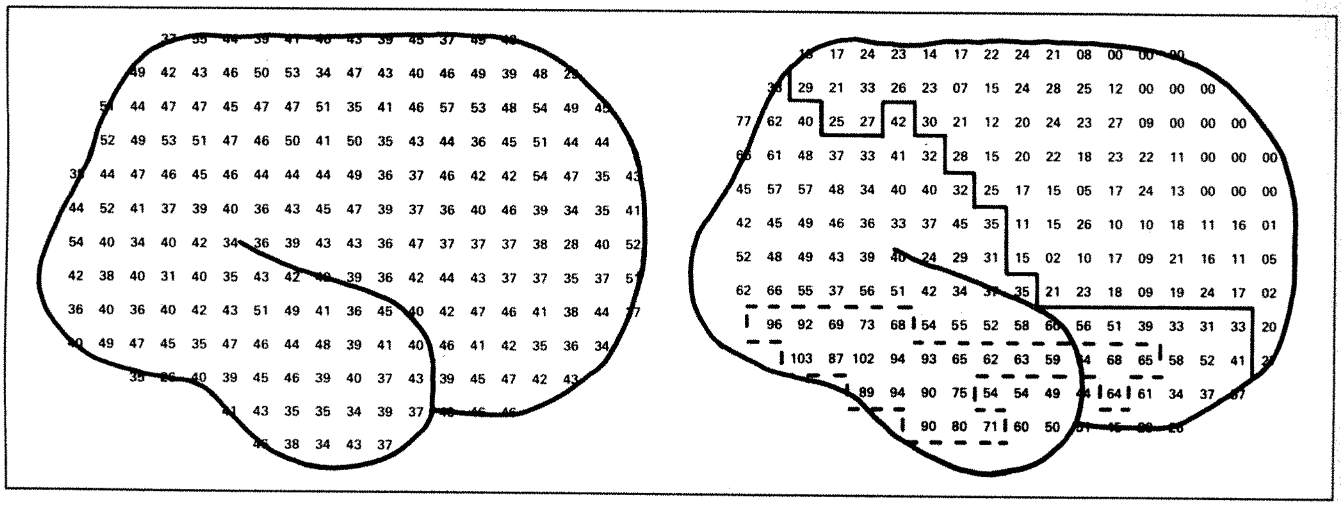

Fig 2.—An example of calculated mean regional cerebral blood flow (rCBF) values (in milliliters per 100 g per minute) as displayed on the printer (case 5). Each value represents data from one detector (1 cm²). During flow 1 (left), there was a normal rCBF distribution. During flow 5 (right), regions of hyperperfusion and hypoperfusion developed. The full line encircles the hypoperfused region, which includes values more than 20% below mean blood flow in unaffected brain regions. Broken line encircles the hyperperfused region, which includes values more than 40% above blood flow in unaffected brain regions. Note the gradually decreasing flow values when moving from high- to low-flow regions owing to the Compton scatter effect (see text).

without signs of arterial occlusions. In one patient (case 3), angiography failed to demonstrate a smaller parietal branch of the middle cerebral artery. One patient (No. 5) had slight hypertension (blood pressure, 170/100 mm Hg) and discrete angiographic signs of a small plaque in the right (relevant) internal carotid artery, just above the bifurcation. The patient was given antithrombotic therapy (warfarin [Coumadin] sodium) for 6 months. It cannot be ruled out that this slight pathological change in case 5 could have caused the symptoms. In none of the patients were there spasms of the arteries visible on the angiogram.

Isotope Arrival

The initial part of the plotted curves indicates the time of arrival of the isotope. In normally perfused brain tissue, a maximum count rate occurs 2 to 4 seconds after the bolus injection. Tight narrowing or occlusions of large arteries will cause an overdue arrival of the isotope.

Group 1.—There was a normal time of arrival in normally perfused brain regions. In regions of infarcts caused by vascular occlusions, maximum count rates were considerably delayed, two to three times later than in normally perfused regions. This was most marked in regions with cortical infarcts and less pronounced in regions overlying subcortical infarcts. Furthermore, vascular spikes were not recorded when an artery was occluded proximal to the location of the detector.

Group 2.—The initial part of the clearance curves from this group of patients showed a normal time of arrival of the isotope in all cortical regions irrespective of low, normal, or high blood flow being recorded from a region. An exception, however, was the delayed isotope arrival in a small subcortical infarct area in the parietal lobe of case 3.

Clinical Observations

In all patients, the degree of paresis was evaluated in accordance with the Medical Research Council score.

Group 1.—In this group, we observed no exacerbation of previous symptoms or development of new symptoms in connection with the examination.

Group 2.—Clinical symptoms are listed in Table 1. In two patients with stroke, there was aggravation of previous symptoms. In two patients with TIA, a new attack developed. All observed symptoms were transient, leaving no permanent sequelae. Two patients exhibited no exacerbation of previous symptoms or development of new symptoms. In none of the patients did headache develop.

Other Observations

During the rCBF measurements, blood pressure, heart rate, and P_{CO_2} were within the normal range. There was no history of cardiac disease in the six patients of group 2. In all cases, the electrocardiogram showed normal sinus rhythm, and there were no signs of atrioventricular block, hypertrophy, or other types of cardiac abnormalities. In none of the patients were there clear indications as to a direct known cause of TIA or stroke. They did not receive any kind of acute medical or surgical therapy. After discharge from the hospital, the patients returned for ambulatory visits regularly for the following 6 months. During this period, the patients' conditions seemed to be fairly stable. One month after the examination, patient 4 experienced one TIA lasting 10 minutes. In patient 3, postinfarct epilepsy developed, and the patient had two generalized seizures within the observation period. In the remaining four patients, there were no clinical signs of further attacks. There were no clinical signs of improvement of the persisting symptoms in patients 1 and 6 (Table 1).

COMMENT

The observation of development of pronounced focal hypoperfusion suggests that focal ischemia due to arteriolar spasms was able to be elicited in the six patients of group 2 on whom we will focus this discussion.

Most likely, the severity and duration of neurological symptoms, associated with the presence of cerebrovascular instability, are proportional to the number and duration of periods during which ischemic flow values are present, as well as to the degree of flow reduction. The magnitude of the flow reduction was not uniform in the unstable perfused regions, that is, some areas within these regions were more severely affected than others (Fig 1).

The transient aggravation of motor and sensory deficits observed during and after the examination of four of the patients described herein were most likely due to transient ischemia in the corresponding motor and sensory zones.[5] The cortical neuronal function might also have been affected by is-

chemia in the two patients who did not exhibit detectable neurological deficits in association with the examination. Insufficient function of cortical areas outside motor and sensory zones may not have been detected if the effect was transient and mild.

Ischemic Threshold

In this study, we refer to the ischemic threshold, defined as the level at which normal neuronal function of the cerebral cortex is affected owing to insufficient blood perfusion. This threshold has been determined to be around 23 m·100 g^{-1}·min^{-1}.[7-10] In our study, we calculated mean rCBF from 48-second intervals. In the hypoperfused regions, mean rCBF was found to be from 13 to 36 mL·100 g^{-1}·min^{-1}. However, these values are considerably overestimated owing to scattered radiation (Compton scatter) in low-flow regions originating from normal or highly perfused surroundings. Olsen et al[11,12] have shown that about 50% of the radiation recorded from the developed low-flow areas is scattered radiation. Therefore, the actual average blood flow in the low-flow areas most likely is around or below the ischemic threshold. As the Compton scatter effect is of greatest importance in low-flow regions close to normal or highly perfused regions, it is not possible to determine the exact extension of a low-flow area. The borders are blurred, and measured flow values are successively decreased from high- to low-flow regions. This is illustrated in Fig 2.

It is not likely that the decrease of blood flow was due to primary physiological deactivation, as complete pharmacological inhibition of the total hemisphere (which excludes Compton effect) only reduces blood flow down to the baseline level, around 22 mL·100 g^{-1}·min^{-1}.[13]

Arteriolar Spasms and Significance of Cerebrovascular Instability

Cerebral angiography did not reveal signs of large-vessel occlusions or spasms of the arteries visible on angiography in the six patients herein described. In one patient (case 3), there was occlusion of a small parietal branch of the middle cerebral artery, and the computed tomographic scan revealed a small subcortical parietal infarct. However, in this case, the abnormally perfused regions were much more widespread than the extension of the infarct area. Most of the frontal lobe and some of the temporal and parietal lobes were affected.

During all rCBF measurements, there were normal temporal and spatial isotope distribution in the territories of the main brain arteries.[3] The isotope angiograms[14] were without signs of occlusions, except in the small infarct area of case 3. We believe that the combination of the fluctuating extension of focal hyperperfused and hypoperfused regions and the absence of signs of occlusion on the arteriogram and isotope angiograms can exclude occlusions of major arteries.

Recently, a condition of cerebrovascular tone instability has been defined as transient spasms of the arterioles alternating with normal calibration of these vessels and/or short periods of vasodilation.[15,16] When arteriolar spasms are present, the blood flow decreases to values consistent with ischemic levels. It is likely that regulation of vascular tone is beyond normal control in the affected, abnormally perfused regions. It was suggested that the arteriolar spasms must be considered the primary event, and the vasodilation causing episodes of hyperemia may be posthypoxic vasodilation or an overshot by compensating mechanisms. The examination procedures used herein, ie, carotid puncture, indwelling catheter, and intracarotid bolus injections, are known to be able to induce the development of focal cerebral hypoperfusion, transient focal ischemia, and a migraine attack in patients suffering from classic and hemiplegic migraine.[15-18] The exact mechanism of this phenomenon is not known. Most likely, the vascular changes in the patients with TIA and stroke reported herein also were triggered of by one or several of the procedures performed in connection with the cerebral angiography and rCBF measurements.

Repeated bolus injections of contrast medium, isotope solution, and heparinized saline might be a strong provocative factor causing release of vasoactive substances from platelets, endothelium, or perivascular nerves. Mowat et al[19] have reported that a few seconds after a bolus of saline or ^{133}Xe solution was injected into the renal artery of healthy dogs, a drastic fall in renal blood flow was observed. Most likely this was due to transient constriction on the afferent arteriolar level. The eliciting of a similar arterio-arteriolar reflex in the vessels supplying the brain could be the primary provoking factor of arteriolar spasms and cerebrovascular instability. Another possible provoking factor might be release of vasoactive substances, such as serotonin, from mechanically damaged platelets. However, the characteristic flow changes reported herein only seem able to be provoked in subjects who are hypersensitive to the triggering factor(s), that is, in patients suffering from classic and hemiplegic migraine and apparently in a group of patients with TIA and stroke as reported here.

Cerebrovascular Instability: Consequence or Cause of TIA and Stroke

The unstable blood flow regulation observed might be a consequence of previous ischemic accidents. However, it was only observed in these six patients, who had no obvious thromboembolic sources, and not in the rest of the examined patients. It might be possible that the condition of cerebrovascular instability also was present during previous spontaneous attacks of transient focal ischemia in these six patients. In our material, the incidence of cerebrovascular instability able to be provoked was found in six (11%) of 53 patients with TIA and stroke without a history of migraine. This incidence could be considered the normal occurrence of hypersensitive subjects in the population. However, this is probably not the case. It has been reported that development of neurological symptoms in connection with intracarotid angiography and rCBF measurements only occurred with an overall rate of 1.3% in nearly 4000 patients examined for a variety of diseases.[20] Therefore, it is likely that the occurrence rate of hypersensitive subjects among patients with TIA and stroke is much higher than normally found in the population as a whole. According to our experience, the highest incidence of hypersensitive subjects is probably found in the group of patients suffering from classic and hemiplegic migraine, in which cerebrovascular instability and transient neurological deficits are able to be provoked in approximately 60% to 70% of cases. Although the recovery from a vascular migraine attack generally is complete, there are reports indicating that permanent neurological sequelae can develop in connection with an attack.[12,21-23] Furthermore, Fisher[24,25] has suggested that migraine accompaniments can cause otherwise unexplained TIA.

It seems likely that attacks of cerebrovascular instability can occur spontaneously in hypersensitive patients, as the provoked symptoms usually are exactly like those experienced during spontaneous attacks. Vasoconstrictor-induced focal cerebral ischemia might be associated with or even the cause of TIA and stroke in patients who have a normal angiographic and cardiac status. On the other hand, abnormal angiography or the finding of cardiac disease does not exclude the coexistence of hypersensitivity to vasospastic stimuli. It should also be considered that a disposition for episodes of cerebrovascular instabilty might be a cause of a previous ischemic event. This might partly explain the unstable clinical condition and fluctuation of neurological deficits seen in some patients with stroke and TIA after a focal cerebral ischemic event.

Gangliosides in Cerebrospinal Fluid in 'Probable Alzheimer's Disease'

Kaj Blennow, MD, PhD; Pia Davidsson, PhD; Anders Wallin, MD, PhD; Pam Fredman, PhD;
Carl-Gerhard Gottfries, MD, PhD; Ingvar Karlsson, MD, PhD;
Jan-Eric Månsson, PhD; Lars Svennerholm, MD, PhD

• The concentrations of the four major brain gangliosides—GM$_1$, GD$_{1a}$, GD$_{1b}$, and GT$_{1b}$—were determined in cerebrospinal fluid from 43 patients with "probable Alzheimer's disease" and 19 healthy controls. Alzheimer's disease was divided into type I (with the memory disturbances and predominant cortical parietal symptoms that are characteristic of Alzheimer's disease) and type II (with general cognitive and mild confusional symptoms, with or without only mild parietal symptoms). The GM$_1$ concentration was significantly higher in patients with Alzheimer's disease type I than in those with Alzheimer's disease type II and age-matched controls, but did not differ significantly between patients with Alzheimer's type II and age-matched controls. As gangliosides are enriched in nerve cell membranes, preferentially in synapses, the findings suggest more severe degeneration of cortical nerve cells in patients with Alzheimer's disease type I than in those with Alzheimer's disease type II.

(*Arch Neurol.* 1991;48:1032-1035)

Alzheimer's disease (AD) is characterized by progressive dementia with memory disturbances and, in typical cases, cortical parietal symptoms.[1-3] The traditional neuropathologic findings in patients with AD consist of degeneration of the cerebral cortex, with a marked loss of neurons and an increased number of senile plaques and neurofibrillary tangles compared with nondemented individuals of the same age.[4-8]

In previous studies in our department, it has been suggested that among patients fulfilling the NINCDS-ADRDA criteria for "probable AD,"[9] two subgroups of patients can be delimited based on their clinical symptoms: AD type I and AD type II.[10-13] Alzheimer's disease type I is characterized by the classic cortical temporoparietal symptoms, low age at onset, low frequency of concomitant vascular diseases, normal blood-brain barrier function, and low frequency of white-matter lesions and has, therefore, been suggested to constitute "classic" or "pure" AD.[10-13] Alzheimer's disease type II is characterized by less cortical and more generalized symptoms of general cognitive and confusional symptoms, high age at onset, high frequency of concomitant vascular diseases, mildly impaired blood-brain barrier function, and high frequency of white-matter lesions, suggesting that a combination of relatively mild Alzheimer encephalopathy, age-related changes, and vascular changes (disease of small blood vessels with white-matter lesions) may be involved in the pathogenesis of dementia, ie, in the production of dementia symptoms, in patients with AD type II.[10-13]

Gangliosides are sialic acid–containing glycosphingolipids that are present in all cells of the body.[14] The concentration of gangliosides is highest in the brain; in the cerebral cortex, it is about three to five times as high as in the white matter.[15-17] The four major gangliosides—GM$_1$, GD$_{1a}$, GD$_{1b}$, and GT$_{1b}$—have been found to be most abundant in the nerve endings (synaptosomes),[18,19] and particular enrichment of the ganglioside GM$_1$ has been demonstrated in the synaptic junction.[20] The gangliosides are located in the outer layer of the plasma membrane[14] and are, to a certain extent, released into the intercellular space in the course of the normal cell surface turnover, a process called "cell surface shedding."[21] Because the intercellular space is in direct contact with the cerebrospinal fluid (CSF),[22] the shedding of gangliosides is reflected in the CSF.[23]

In diseases like AD, which are characterized by progressive degeneration of neurons, an increased release of gangliosides into CSF can be expected. Therefore, we decided to investigate CSF for its content of gangliosides in AD and to evaluate their use as indexes of neuronal degeneration and as biologic markers of AD.

PATIENTS, SUBJECTS, AND METHODS

Patients

Forty-three patients with probable AD[9] were included in the study (15 men and 28 women; 54 to 87 years of age; mean ± SD age, 71.3 ± 8.2 years). All patients underwent a thorough clinical investigation, including a medical history, physical examination, neurologic and psychiatric examinations, screening laboratory tests, electrocardiography, chest roentgenography, electroencephalography, and computed tomography of the brain. Patients with a history of major psychiatric or neurologic disorders, alcoholism, or major head trauma were excluded, as were those with manifest or suspected other primary (eg, Pick's disease, Parkinson's dis-

ease, and progressive supranuclear palsy) or secondary (eg, depression, metabolic disturbances, and toxic effects) causes of dementia. Patients with a history of transient ischemic attacks or stroke episodes, occurrence of pronounced vascular factors, or computed tomographic scan findings of infarcts were also excluded. Thus, the diagnosis of "probable AD" was made in accordance with the NINCDS-ADRDA criteria,[9] ie, after the exclusion of all other known disorders that could account for the dementia.

The patients fulfilling the NINCDS-ADRDA criteria for "probable AD"[9] were divided into two groups—AD type I and AD type II—based on their clinical symptoms.[10,11] The AD type I group consisted of five men and seven women, aged 54 to 72 years, with a clinical picture of memory disturbances together with predominant cortical parietal symptoms, while the AD type II group consisted of three men and seven women, aged 69 to 87 years, with memory disturbances, general cognitive symptoms, and mild confusional symptoms, but with absence of or only mild parietal symptoms.[10,11] The importance of adequate matching for severity of dementia in studies concerning clinical symptoms in demented patients has been emphasized, as the prevalence of brain regional symptoms is dependent on the severity of dementia,[24] ie, parietal symptoms may be absent in mildly demented patients.[1-3,10] For this reason, mildly demented patients were excluded from the AD type I and AD type II groups. All clinical diagnoses and assessments of clinical symptoms were made without knowledge of the results of the analyses of the ganglioside concentrations in CSF and vice versa.

Controls

The controls included 13 men and six women, aged 55 to 77 years, admitted for minor surgery (ie, coxarthrosis and prostate hyperplasia) involving spinal anesthesia. No controls had histories, symptoms, or signs of psychiatric or neurologic disease, malignant disease, or systemic disorders (eg, rheumatoid arthritis and infectious disease). The cognitive status was evaluated using the Mini-Mental State examination.[25] Individuals with scores below 28 were excluded.

As we had found low negative correlations between CSF gangliosides and age in a larger control sample with an age range of 18 to 85 years (unpublished data), the control group was divided into one younger and one older group for age matching with the AD type I and AD type II groups. However, in the control group in this study (n = 19; 51 to 77 years of age), no significant correlations were found between CSF gangliosides and age (data not shown) and no significant differences were found in CSF gangliosides between the younger and older control groups (Table 1).

Methods for CSF Analysis

Lumbar punctures were performed in the L3-4 or L4-5 interspace. A volume of 12 mL of CSF was collected in silicone-coated tubes and gently mixed to avoid gradient effects. A blood sample was taken at the same time. All CSF samples with more than 500 erythrocytes per microliter were excluded.

Quantitative determination of albumin in serum and CSF was performed by rocket immunoelectrophoresis.[26] The albumin ratio (CSF albumin [in milligrams per liter] divided by serum albumin [in grams per liter]) was used as the measure of the blood-brain barrier function.[27]

Concentrations of gangliosides GM$_1$, GD$_{1a}$, GD$_{1b}$, and GT$_{1b}$ were individually determined with an anticholera toxin B subunit monoclonal antibody after chromatography and sialidase hydrolysis of GD$_{1a}$, GD$_{1b}$, and GT$_{1b}$ to GM$_1$ and incubation with cholera toxin B subunit on high-performance, thin-layer plates.[28] The sensitivity of this method is 50 fmol of GM$_1$ per liter, the within-run imprecisions are 7% to 9%, and the between-run imprecisions are 12% to 14%.[28] The binding of cholera toxin to ganglioside GM$_1$ is highly specific.[29] The production and the specificity of the monoclonal antibody to cholera toxin B subunit have been described previously.[30]

Statistical Analysis

For comparisons between groups, the Wilcoxon two-sample test was used for quantitative parameters and the χ^2 test for qualitative parameters. The Spearman Rank Correlation Coefficient was used for correlations.

The study was approved by the Ethics Committee of the University of Göteborg, Sweden. The patients with AD (or their nearest relatives) and the controls gave their informed consent to participate in the study.

RESULTS

The mean age did not differ significantly between patients with "probable AD" (n = 43; mean ± SD age, 71.3 ± 8.2 years) and controls (n = 19; mean ± SD age, 67.2 ± 8.5 years), between patients with AD type I (n = 12; mean ± SD age, 64.8 ± 5.3 years) and younger controls (n = 10; mean ± SD age, 61.3 ± 7.3 years), or between patients with AD type II (n = 10; mean ± SD age, 78.0 ± 6.1 years) and older controls (n = 9; mean ± SD age, 73.8 ± 2.0 years). The severity of dementia did not differ between patients with AD type I and AD type II, as the groups were matched for this variable (see "Patients, Subjects, and Methods" section). The duration of dementia did not differ significantly between patients with AD type I (6.8 ± 2.4 years) and AD type II (5.2 ± 3.0 years).

No significant correlations were noted between the albumin ratio and the total CSF ganglioside concentration in patients with "probable AD" ($r = -.08$) or in controls ($r = .07$), nor did any of the four individual brain gangliosides show significant correlations with the albumin ratio (data not shown).

The mean concentrations of gangliosides in patients with probable AD and controls are shown in Table 2. The total concentration of the four brain gangliosides were not found to differ significantly, but there was a changed proportion of gangliosides between the groups: there was an increase in GM$_1$ (222%; 25.6 for "probable AD" vs 11.2 for controls) and GD$_{1a}$ (188%; 39.0 for "probable AD" vs 20.8 for controls) compared with controls, while GT$_{1b}$ was decreased (79%; 29.4 for "probable AD" vs 37.4 for controls).

When patients with AD type I and age-matched controls were compared, the difference in the GM$_1$ concentration was even more pronounced (273%; 32.8 for AD type I vs 12.0 for controls), while the difference in the GD$_{1a}$ concentration did not reach statistical significance (161%; 34.8 for AD type I vs 21.6 for controls) (Table 1). GD$_{1b}$ concentration, GT$_{1b}$ concentration, or the total concentration of the four gangliosides did not

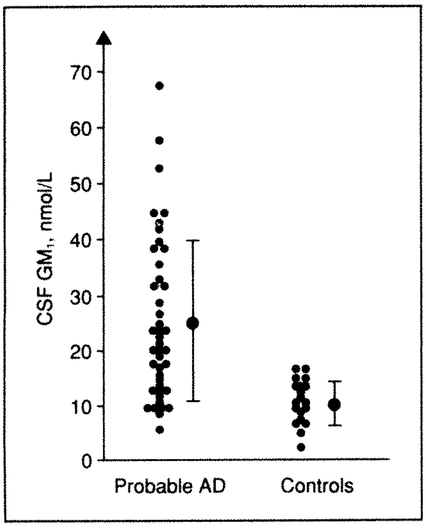

Fig 1.—Individual and mean ± SD (vertical bars) values for cerebrospinal fluid (CSF) GM_1 concentration in patients with "probable Alzheimer's disease" (AD) and age-matched controls. "Probable AD" vs controls, $P < .0001$.

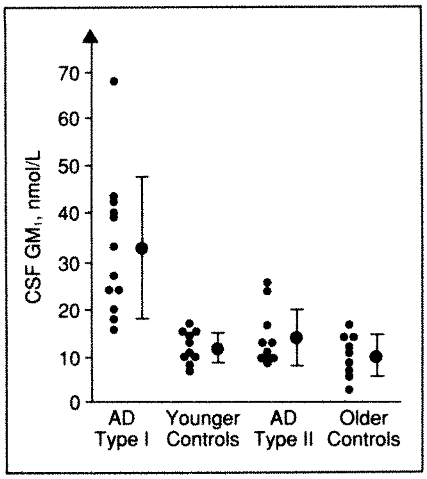

Fig 2.—Individual and mean ± SD (vertical bars) values for cerebrospinal fluid (CSF) GM_1 in patients with Alzheimer's disease (AD) type I, AD type II, and age-matched controls. Patients with AD type I vs younger controls, $P < .0001$; patients with AD type I vs patients with AD type II, $P < .001$; and patients with AD type II vs older controls and younger controls vs older controls, not significant.

differ significantly. The GM_1 concentration was also significantly higher in patients with AD type I compared with those with AD type II (231%; 32.8/14.2), while GD_{1a}, GD_{1b}, GT_{1b}, and the total concentration of the four gangliosides did not differ significantly. No significant differences in CSF gangliosides were noted between patients with AD type II and age-matched controls.

Figures 1 and 2 show the individual GM_1 values. Most (65%; 28/43) patients with probable AD had higher GM_1 values than controls, but there was substantial overlap, as 15/43 (35%) of patients with "probable AD" had GM_1 values that were within the range of the control values (Fig 1). In the AD type I group, one of 12 patients had a GM_1 value that was within the range of control values (Fig 2). In contrast, eight (80%) of 10 patients with AD type II had GM_1 values that were within the range of control values (Fig 2).

COMMENT

Only recently have methods been developed to investigate ganglioside concentrations in the CSF of individual patients.[23,28] Consequently, the potential of CSF gangliosides to reflect changes in the central nervous system ganglioside metabolism and degeneration of ganglioside-rich membranes has not been fully established. Several studies, however, have suggested that CSF gangliosides are derived from the central nervous system by shedding and thus reflect the release of gangliosides from brain plasma membranes.[23,28,31] The absence, found in our study, of a correlation between the major CSF gangliosides and albumin ratio supports the conclusion that these gangliosides are predominantly derived from the central nervous system and not from the serum. This is further supported by the finding of a different ganglioside pattern in serum than in CSF.[32]

Our study revealed changes in CSF ganglioside concentrations in patients with probable AD. Compared with controls, a marked increase was noted in GM_1 and GD_{1a} concentrations. The increase in GM_1 concentration mainly occurred in patients with AD type I, while the mean GM_1 value for patients with AD type II did not differ significantly from that for age-matched controls. These findings support the relevance of the division of "probable AD" into two types.

The concentration of gangliosides is three to five times as high in the cortex as in the white matter.[15-17] The brain gangliosides are preferentially located to neurons,[14,33,34] but their subcellular location in the neurons is insufficiently known. Some investigators claim that the four major gangliosides—GM_1, GD_{1a}, GD_{1b}, and GT_{1b}—are most abundant in the nerve endings (synaptosomes),[18,19] while others claim that they are distributed over a major portion of the neuronal surface.[34,35] Among the brain gangliosides, the concentrations of GM_1 and GD_{1a} are known to increase during the phase of outgrowth of axons and synaptogenesis in the development of the brain, suggesting a relation between synapses and GM_1 and GD_{1a} gangliosides.[36] GM_1 has also been shown to be enriched in the synaptic junction.[14,20] Thus, one possible explanation for the increase in GM_1 and GD_{1a} concentrations may be that it reflects the severe degeneration of cortical nerve cells and synapses in "probable AD," preferentially in the (younger) AD type I group. Several postmortem studies have shown that the cortical neuronal loss is greater in younger than in older patients with AD.[8,37-39] However, the increase in CSF GM_1 concentration in the younger AD type I group is not attributable to age differences, as no difference in CSF GM_1 was noted between the older and younger control groups and no increase in the older AD type II group compared with age-matched controls. The difference in CSF GM_1 concentration between the AD type I and AD type II groups is not caused by different severity of dementia, as the groups were matched for this parameter (see "Patients, Subjects, and Methods" section).

Among the gangliosides, GM_1 was found to have the highest discriminative capacity between groups. Although the GM_1 concentration was considerably higher in patients with "probable AD" than in controls, there was substantial overlap (Fig 1). However, the concentration of GM_1 in CSF discriminated patients with AD type I from controls, as well as from patients with AD type II: only one (10%) of 10 controls and two (20%) of 10 patients with AD type II had CSF GM_1 values within the range of the AD type I group. These findings suggest that GM_1 may be a biologic marker of pure AD (AD type I). Further studies are needed to elucidate the potential of CSF GM_1 concentration as a biologic marker for AD type I. Our intention is to further investigate its sensitivity in studies on larger patient and control samples and its specificity in studies including patients with diseases, such as Pick's disease, that are also characterized by neuronal and synaptic degeneration. Preliminary results of studies on vascular dementia reveal low CSF GM_1 values, comparable with those in patients with AD type II and in controls.

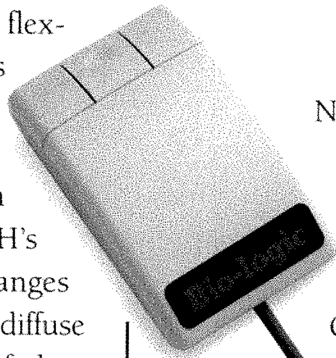
offers increased depth of analysis and flexibility. Now you can have instant access to any area of interest. The ability to reformat previously acquired records allows you to view the same tracings with different montages. And CEEGRAPH's capability to emulate paper speed changes after the fact lets you easily view areas of diffuse activity or enhance the periodicity of slow wave bursts.



F EVOLUTION

Increase your capabilities without sacrificing speed.

With CEEGRAPH, you can reveal more information, without extending test and review time. You can easily localize events, "zoom" in on waveforms, have instant access to precise amplitude, duration and frequency measurements, locate annotated events, and more. Everything including calibration, impedance testing and actual EEG testing operates the same as traditional EEG, but with the benefits of digital EEG technology.

Don't get left behind.

Now is your opportunity to invest in the future. If you're looking to replace or add an EEG instrument, you owe it to your lab to see a demonstration of CEEGRAPH and see the evolution. From individual components that work with your existing EEG instrument to a complete digital EEG system, CEEGRAPH grows with your lab to enhance your capabilities. And CEEGRAPH is your entry into the Bio-logic totally integrated electrodiagnostic laboratory, from EP and EMG to brain mapping and polysomnography.

Find out how the power of evolution can bring your lab advanced capabilities. Call 1-800-323-8326* to talk to one of our representatives or to receive a FAX report of CEEGRAPH's unique features and benefits.

Paired Associate Learning in Senile Dementia of the Alzheimer Type

Janet M. Duchek, PhD; Marshall Cheney, MA; F. Richard Ferraro, PhD; Martha Storandt, PhD

• A study was conducted to examine the potential explicit learning ability in senile dementia of the Alzheimer type (SDAT) as a function of (1) the difficulty of the to-be-remembered material and (2) the severity of the dementia. The Associate Learning task from the Wechsler Memory Scale was administered to healthy older adults and individuals with questionable, mild, and moderate SDAT. Individuals with SDAT showed poorer learning performance across trials than healthy older adults. Individuals with questionable and mild SDAT did show evidence for learning across trials for highly related paired associates. For unrelated-paired associates, however, only individuals with questionable SDAT showed some evidence for increased learning across trials.

(*Arch Neurol.* 1991;48:1038-1040)

Memory loss is a hallmark clinical symptom of the mild stages of senile dementia of the Alzheimer type (SDAT). Previous articles from the Washington University Memory and Aging Project have revealed a marked memory deficit associated with SDAT on a variety of psychometric measures.[1-3] Although it is clear that the overall memory performance of patients with SDAT is impaired compared with healthy older adults, it is not entirely clear whether patients with SDAT can demonstrate any learning across trials.

There is some evidence for learning in SDAT with implicit memory tasks in which the prior experience with the task facilitates performance without having to consciously recollect the prior experience. It has been reported that individuals with SDAT benefit as much as healthy older adults from the repeated exposure to items in a mirror reading task[4] and a semantic priming task.[5] People with SDAT also demonstrate implicit learning of motor tasks. For example, Knopman and Nissen[6] reported that patients with SDAT demonstrated learning of a repeated motor sequence across blocks of trials. Also, Heindel et al[7] found nearly identical learning curves for healthy older adults and patients with SDAT in a pursuit-rotor task.

The memory performance deficit associated with SDAT across many psychometric measures, however, involves explicit memory such as recall and recognition tasks. Individuals with SDAT exhibit large deficits in explicit memory tasks, but relatively little attention has been paid to explicit learning in SDAT. In the mild stages of the disease, individuals exhibit a typical U-shaped serial position curve.[8] That is, items from the beginning (ie, primacy) and end (ie, recency) of the list are better recalled than items from the middle of the list. It has been argued that the primacy effect reflects long-term memory processes, whereas the recency effect reflects short-term memory processes.[9] Thus, at least in the early stages of SDAT there is some evidence that material can be stored in a more durable long-term store. As the severity of the disease increases, however, the primacy effect diminishes followed finally by a loss of the recency effect.[8,10,11]

Other studies have examined the acquisition of new information by focusing on the learning curves of patients with SDAT across trials.[10,12] In both studies patients with SDAT exhibited a relatively flat learning curve. Little et al[13] reported that individuals with SDAT were able to retain paired associates over a 2-month interval, yet showed no evidence for increased retention across testing. Thus, unlike the implicit memory tasks, there appears to be little evidence for learning across trials in explicit memory tasks. It is possible, however, that individuals with SDAT can learn new information as a function of different task requirements.

The purpose of our study was to examine the potential explicit learning ability in SDAT as a function of (1) the difficulty of the to-be-remembered material and (2) the severity of the dementia. This was performed using the Associate Learning subtest from the Wechsler Memory Scale,[14] which involves the learning/retention of both easy and difficult paired associates across three trials. The task was administered to healthy control subjects and individuals with questionable, mild, and moderate SDAT. There have been previous articles of summary scores from this subtest with portions of the sample included herein.[1-3,15-17]

SUBJECTS AND METHODS

Participants in the patient registry of the Washington University Alzheimer's Disease Research Center, St Louis, Mo, were originally screened by physicians for depression,

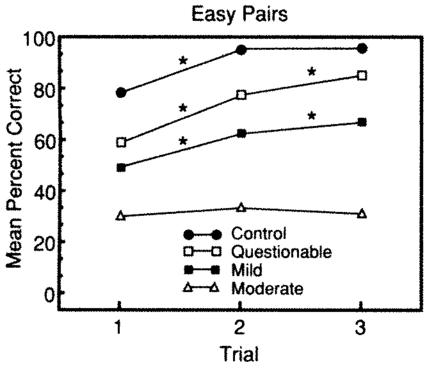

Fig 1.—Mean percent correct recall for easy pairs as a function of group and trial. Asterisk indicates a statistically significant increase between trials.

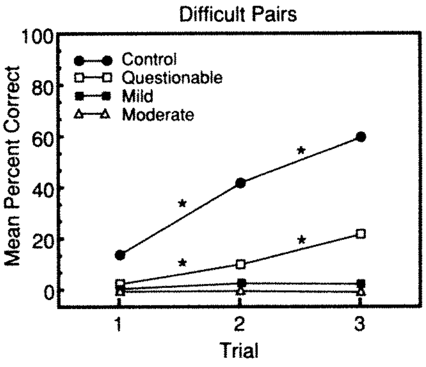

Fig 2.—Mean percent correct recall for difficult pairs as a function of group and trial. Asterisk indicates a statistically significant increase between trials.

severe hypertension, reversible dementias, or other disorders or medications that could potentially produce cognitive impairment.[18] The severity of the dementia was staged according to the Washington University Clinical Dementia Rating (CDR) scale where CDR 0, 0.5, 1, 2, and 3 represent no dementia, questionable, mild, moderate, and severe dementia, respectively.[19,20] The label "questionable dementia" (CDR 0.5) was initially used for individuals with very mild cognitive impairment such that the clinician was unsure whether the impairment would progress to SDAT until further longitudinal data had been collected. In fact, over time, the majority of these individuals clinically progressed to more severe stages of SDAT or Alzheimer's disease was verified post mortem. Thus, these results indicate that the CDR 0.5 represents a "very mild" stage of SDAT.[21-23]

In this analysis, there were 83 individuals who had a CDR of 0, 41 who had a CDR of 0.5, 66 who had a CDR of 1, and 21 who had a CDR of 2. Only data from the first time of testing were examined for those individuals enrolled for longitudinal study.

The diagnosis and staging of the disease is based on a 90-minute examination and interview with both the participant and a collateral source. The CDR is derived from the physicians' evaluation of the individual's cognitive abilities in the areas of memory, orientation, judgment and problem-solving, community affairs, home and hobbies, and personal care. The reliability of the CDR and validity of the diagnosis have been reported elsewhere in the literature.[24-26]

The Wechsler Memory Scale[14] was administered as the first part of a 2-hour comprehensive psychometric battery that assesses various aspects of memory, psychomotor performance, and language.[2,3] The subtest measuring visual memory was omitted.

The Associate Learning subtest consists of a list of 10 paired associates. Six of the pairs are easy (ie, related) associates (eg, metal-iron) and four of the pairs are difficult (ie, unrelated) associates (eg, crush-dark). The 10 pairs are presented in a different order on each of three trials.

All participants were tested individually by a trained psychometrician. The test was administered and scored according to standard instructions. On the first trial, the list of 10 pairs was read to the participant. Following the presentation of the list, the psychometrician read the first word of each pair (eg, metal) and the participant was asked to respond with the word paired with the first word (eg, iron). The same procedure was followed on the second and third trials.

RESULTS

The percent correct recall for each person was calculated for easy and difficult pairs on each of the three trials. The easy and difficult pairs were analyzed separately. These data were analyzed using a 4 × 3-mixed factor analysis of variance. Group (healthy control, questionable dementia, mild dementia, moderate dementia) was the between-subject factor and trial (1, 2, or 3) was the within-subject factor.

The data from the easy pairs are presented in Fig 1 as a function of group and trial. There are four findings to note. First, the healthy control subjects overall showed better performance than all three SDAT groups. Second, the questionable SDAT group showed increasing performance across trials. Third, the mild SDAT group also showed increasing performance across trials 1 and 2 and a slight increase at trial 3. Fourth, the moderate SDAT group showed the same level of performance across all three trials.

These observations were supported by the following analyses. The overall analysis of variance indicated there was a significant main effect of group, F(3,207)=78.1, mean square error (MSe)=7.41, and trial, F(2,414)=71.19, MSe=1.31, and a group × trial interaction, F(6,414)=4.48, MSe=.08. Post hoc analyses indicated that the questionable SDAT group showed a significant increase in performance from trial 1 to trial 2, F(1,40)=34.23, MSe=.81; and trial 2 to trial 3, F(1,40)=8.35, MSe=.12. The mild SDAT group also showed a significant increase in performance from trial 1 to trial 2, F(1,65)=30.74, MSe=.66; and a slight increase from trial 2 to trial 3, F(1,65)=4.14, MSe=.07, *P*=.05, although the slope of the learning curve was greater for the questionable (13.8) than the mild SDAT group (9.35).

The data from the difficult pairs are presented in Fig 2. There are three findings to note. First, the healthy control subjects showed better performance across trials than all three SDAT groups. Second, the questionable SDAT group showed increasing performance across trials. Third, both the mild and moderate SDAT groups' performance represents a floor effect.

These observations were supported by the following analyses. The overall analysis of variance indicated there was a significant main effect of group, F(3,207)=73.59, MSe=6.62, and trial, F(2,414)=66.00, MSe=1.34, and a group × trial interaction, F(6,414)=37.97, Mse=.77. Post hoc analyses indicated that the questionable SDAT group showed a significant increase in performance from trial 1 to trial 2, F(1,40)=12.56, MSe=.15; and trial 2 to trial 3, F(1,40)=14.87, MSe=.30.

COMMENT

The purpose of this study was to examine the explicit learning ability in SDAT as a function of (1) the difficulty of the to-be-remembered material and (2) the severity of the dementia. The results are straightforward with respect to both issues.

It is clear that SDAT individuals show poorer learning performance across trials than healthy older adults even when the to-be-remembered material is relatively easy. However, despite the overall lower level of performance, individuals with questionable and mild SDAT did show evidence for increased learning across trials for the easy (ie, highly related) paired associates. On the other hand, individuals in the moderate stage of SDAT showed a relatively flat learning curve across trials for the easy material. Finally, for the difficult pairs, only nondemented individuals or those with questionable SDAT showed some evidence for increased learning across trials. Both the mildly and moderately demented individuals were virtually unable to learn any of the difficult pairs across trials.

This study provides evidence that individuals in the milder stages of SDAT can benefit from the repetition of material across trials in an explicit memory task. As previously mentioned, there is literature supporting learning across trials in SDAT for implicit memory tasks.[4,6,7] There is, however, little evidence for learning in explicit memory tasks, such as recall or recognition, which require the conscious retrieval of information from memory. Bigler et al[10] reported a relatively flat learning curve for early-stage DAT patients across five trials, although performance did increase slightly from the first trial (March 15) to the last trial (May 15). One possible explanation for the failure to demonstrate learning in Bigler and coworkers' study may be due to the type of task used. Learning was assessed with the Rey-Auditory Verbal Learning Test,[27] which involves the free recall of a 15-item list. It has been argued that free recall is a more cognitively demanding task than a cued recall task such as a paired associate task.[28] Thus, it is possible that individuals with SDAT may not show evidence of learning in more cognitively demanding tasks.

Our study provides support that individuals with SDAT can acquire new information that is relatively easy with a less cognitively demanding task, such as cued recall. As previously noted, El-Awar et al[12] used a paired associate task and still found no evidence for learning across 10 trials in patients with SDAT. The list, however, contained 10 unrelated paired associates, which would be similar to the difficult pairs in this study. Thus, the results of El-Awar and coworkers' study are similar to our finding that mildly or moderately demented individuals do not show evidence for learning difficult material across trials.

In conclusion, individuals in the milder stages of SDAT do show evidence for explicit learning ability when the to-be-remembered information is "easy" (ie, makes use of well-established associations in memory). On the other hand, if the to-be-remembered material is more difficult in nature (ie, does not make use of existing associations), individuals even in the least severe stages of Alzheimer's disease show little evidence for learning.

Craik et al[28] argued that the magnitude of the memory deficit associated with normal aging depends on the type of task and materials used, as well as characteristics of the subject population. The more the task and materials support the cognitive processing (eg, a cued recall task), the smaller the age-related memory deficit. One could make a similar argument regarding the learning ability of individuals with SDAT. People with SDAT can learn new information when (1) the disease is not severe, (2) the cognitive demands of the task are minimized, and (3) the to-be-remembered information makes use of existing associations in the memory network. As the disease progresses, however, there is little evidence for learning even when the task and materials support the cognitive processing.

This research was supported in part by National Institute on Aging (Bethesda, Md) grants AGO3991 and AGO5681.

We thank the clinicians at the Washington University Alzheimer's Disease Research Center (St Louis, Mo) for diagnostic assistance and Emily LaBarge, EdD, for psychometric testing.

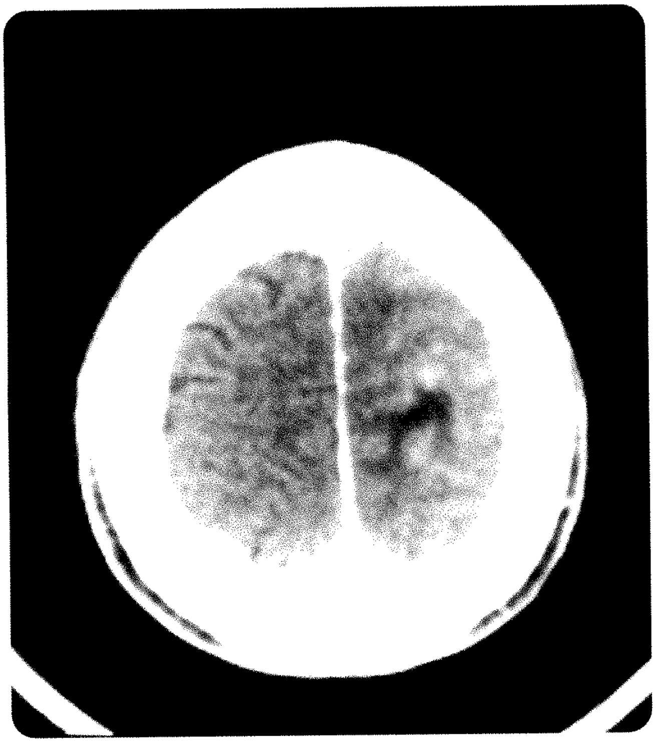
THE DECISION IS YOURS.

COMPARE.

THE CASE: A 40-year-old man presented with a 2-month history of involuntary muscle contractions of the right arm and mild weakness of the left leg.

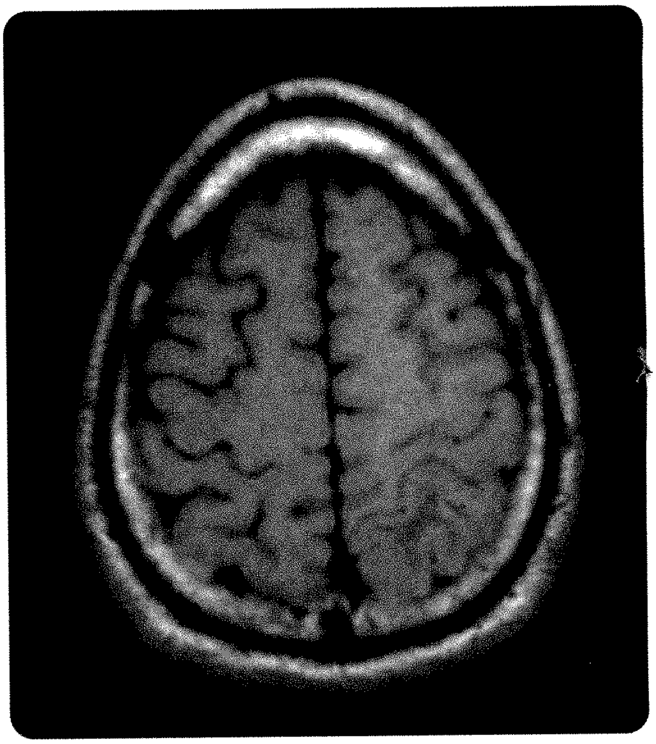
First there was CT.



Contrast CT scan shows an area of low attenuation in the left parietal lobe. A questionable focus of contrast is seen, but this may represent cerebral cortex.

Images courtesy of Michael R. Ross, MD, Stanford University Medical Center, Stanford, California

Then MRI.

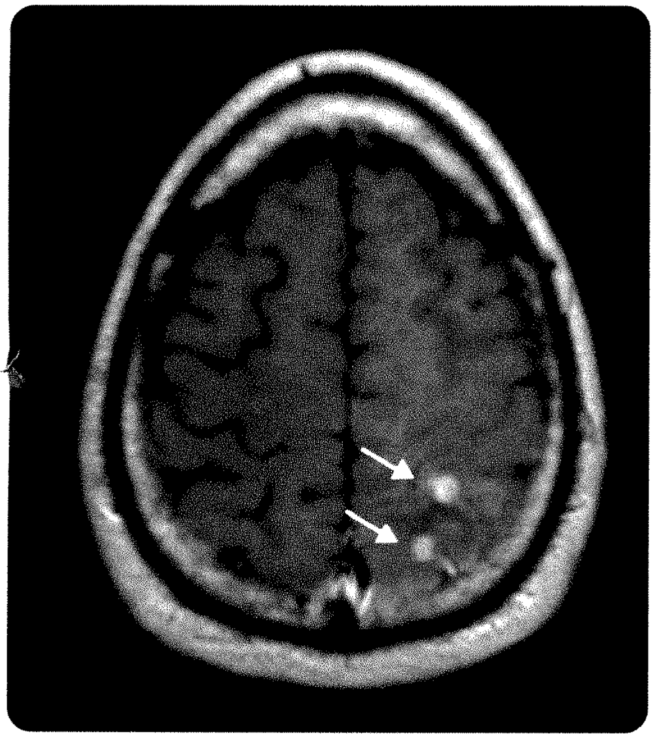


T1-weighted (TR 800/TE 20) unenhanced MR image, obtained with a 1.5-T imager, shows subcortical hypointensity in the left posterior parietal lobe. The surrounding sulci appear to be compressed, but a mass is not clearly appreciated.

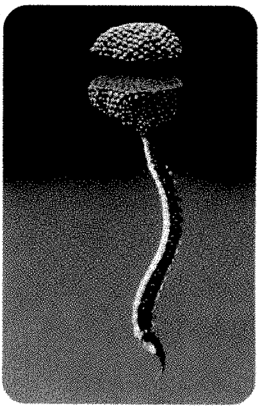
© 1991, Berlex Laboratories, Inc. All rights reserved.

AND CONTRAST.

Now, *Magnevist*®-enhanced MRI lets you see even more.



T1-weighted (TR 800/TE 20) image enhanced with MAGNEVIST® injection reveals two discrete nodules (arrows). This nodular enhancement is highly suggestive of a primary brain tumor, which was confirmed upon biopsy to be an astrocytoma.



Magnevist®

(gadopentetate dimeglumine 469.01 mg/mL)

INJECTION

NOTHING LOCATES LESIONS BETTER

Please see brief summary of prescribing information for MAGNEVIST® injection on last page of this advertisement.

Well tolerated[1] In clinical trials, the most common adverse reactions reported were headache (8.7%) and injection-site coldness/localized coldness (4.8%). The majority of headaches were transient and of mild to moderate severity. In clinical trials, 15% to 30% of patients experienced an asymptomatic transient rise in serum iron; hypotension and anaphylactoid reactions have occurred in less than 1% of the patients. The safety of MAGNEVIST® injection in patients with hemolytic disorders has not been studied.

REFERENCE: 1. Data on file, Berlex Laboratories, Inc.

BRIEF SUMMARY

INDICATIONS AND USAGE

MAGNEVIST® Injection is indicated for use with magnetic resonance imaging (MRI) in adults and children (2 years of age and older) to provide contrast enhancement in those intracranial lesions with abnormal vascularity or those thought to cause an abnormality in the blood-brain barrier. MAGNEVIST® Injection has been shown to facilitate visualization of intracranial lesions including but not limited to tumors.

MAGNEVIST® Injection is also indicated for use with MRI in adults and children (2 years of age and older) to provide contrast enhancement and facilitate visualization of lesions in the spine and associated tissues. There is, however, only limited clinical experience in children for this indication.

CONTRAINDICATIONS

None known.

WARNINGS

The accepted safety considerations and procedures that are required for magnetic resonance imaging are applicable when MAGNEVIST® Injection is used for contrast enhancement. In addition, deoxygenated sickle erythrocytes have been shown in *in vitro* studies to align perpendicular to a magnetic field which may result in vaso-occlusive complications *in vivo*. The enhancement of magnetic moment by gadopentetate dimeglumine may possibly potentiate sickle erythrocyte alignment. MAGNEVIST® Injection in patients with sickle cell anemia and other hemoglobinopathies has not been studied.

Patients with other hemolytic anemias have not been adequately evaluated following administration of MAGNEVIST® Injection to exclude the possibility of increased hemolysis.

Hypotension may occur in some patients after injection of MAGNEVIST® Injection. In clinical trials two cases were reported and in addition, there was one case of a vasovagal reaction and two cases of pallor with dizziness, sweating and nausea in one and substernal pain and flushing in the other. These were reported within 25 to 85 minutes after injection except for the vasovagal reaction which was described as mild by the patient and occurred after 6-1/2 hours. In a study in normal volunteers one subject experienced syncope after arising from a sitting position two hours after administration of the drug. Although the relationship of gadopentetate dimeglumine to these events is uncertain, patients should be observed for several hours after drug administration.

Magnevist®
(gadopentetate dimeglumine 469.01 mg/mL)
INJECTION

PRECAUTIONS - General

Diagnostic procedures that involve the use of contrast agents should be carried out under direction of a physician with the prerequisite training and a thorough knowledge of the procedure to be performed.

In a patient with a history of grand mal seizures, MAGNEVIST® Injection was reported to induce such a seizure.

Since gadopentetate dimeglumine is cleared from the body by glomerular filtration, caution should be exercised in patients with severely impaired renal function.

The possibility of a reaction, including serious, life-threatening, fatal, anaphylactoid or cardiovascular reactions or other idiosyncratic reactions should always be considered (see ADVERSE REACTIONS) especially in those patients with a known clinical hypersensitivity.

Animal studies suggest that gadopentetate dimeglumine may alter red cell membrane morphology resulting in a slight degree of extravascular (splenic) hemolysis. In clinical trials 15-30% of the patients experienced an asymptomatic transient rise in serum iron. Serum bilirubin levels were slightly elevated in approximately 3.4% of patients. Levels generally returned to baseline within 24 to 48 hours. Hematocrit and red blood cell count were unaffected and liver enzymes were not elevated in these patients. While the effects of gadopentetate dimeglumine on serum iron and bilirubin have not been associated with clinical manifestations, the effect of the drug in patients with hepatic disease is not known and caution is therefore advised.

When MAGNEVIST® Injection is to be injected using plastic disposable syringes, the contrast medium should be drawn into the syringe and used immediately.

If nondisposable equipment is used, scrupulous care should be taken to prevent residual contamination with traces of cleansing agents.

Repeat Procedures: If in the clinical judgment of the physician sequential or repeat examinations are required, a suitable interval of time between administrations should be observed to allow for normal clearance of the drug from the body.

Information for Patients:

Patients receiving MAGNEVIST® Injection should be instructed to:

1. Inform your physician if you are pregnant or breast feeding.
2. Inform your physician if you have anemia or any diseases that affect red blood cells.

LABORATORY TEST FINDINGS

Transitory changes in serum iron and bilirubin levels have been reported in patients with normal and abnormal liver function (See PRECAUTIONS - General).

CARCINOGENESIS, MUTAGENESIS, AND IMPAIRMENT OF FERTILITY

No animal studies have been performed to evaluate the carcinogenic potential of gadopentetate dimeglumine.

Gadopentetate dimeglumine did not evoke any evidence of mutagenic potential in the Ames test (histidine-dependent *Salmonella typhimurium*) nor in a reverse mutation assay using tryptophan-dependent *Escherichia coli*. Gadopentetate dimeglumine did not induce a positive response in the (C3H 10T1/2) mouse embryo fibroblast cellular transformation assay, nor did it induce unscheduled DNA repair synthesis in primary cultures of rat hepatocytes at concentrations up to 5000 μg/mL. However, the drug did show some evidence of mutagenic potential *in vivo* in the mouse dominant lethal assay at doses of 6 mmol/kg, but did not show any such potential in the mouse and dog micronucleus tests at intravenous doses of 9 mmol/kg and 2.5 mmol/kg, respectively.

The results of a reproductive study in rats showed that gadopentetate dimeglumine when administered in daily doses of 0.1-2.5 mmol/kg, did not cause a significant change in the pregnancy rate in comparison to a control group. However, suppression of body weight gain and food consumption and a decrease in the mean weights of testis and epididymis occurred in male rats at the 2.5 mmol/kg dose. In female rats a decrease in the number of corpora lutea at the 0.1 mmol/kg dose and the suppression of body weight gain and food consumption at the 2.5 mmol/kg dose were observed.

In a separate experiment, 16 daily intravenous injections were administered to male rats. At a dose of 5 mmol/kg of gadopentetate dimeglumine, spermatogenic cell atrophy was observed. This atrophy was not reversed within a 16-day observation period following the discontinuation of the drug. This effect was not observed at a dose of 2.5 mmol/kg.

PREGNANCY CATEGORY C.

Gadopentetate dimeglumine has been shown to retard development slightly in rats when given in doses 2.5 times the human dose, and in rabbits when given in doses of 7.5 and 12.5 times the human dose. The drug did not exhibit this effect in rabbits when given in doses 2.5 times the human dose. No congenital anomalies were noted in either species.

There are no adequate and well-controlled studies in pregnant women. MAGNEVIST® Injection should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

NURSING MOTHERS

C^{14} labelled gadopentetate dimeglumine was administered intravenously to lactating rats at a dose of 0.5 mmol/kg. Less than 0.2% of the total dose was transferred to the neonate via the milk during the 24-hour evaluation period. It is not known to what extent MAGNEVIST® Injection is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when the drug is administered to a nursing mother and consideration should be given to temporarily discontinuing nursing.

PEDIATRIC USE

Safety and efficacy in children under the age of 2 years have not been established. (See Indications and Usage and Dosage and Administration sections).

ADVERSE REACTIONS

The most commonly noted adverse experience is headache with an incidence of 8.7%. The majority of headaches are transient and of mild to moderate severity. In 42.3% of the cases it was felt that the headaches were not related to MAGNEVIST® Injection. Injection site coldness/localized coldness is the second most common adverse experience at 4.8%. Nausea occurs in 3.2% of the patients.

Localized pain, vomiting, paresthesia, dizziness and localized warmth occur in less than 2% of the patients.

The following additional adverse events occur in less than 1% of the patients:

Body as a Whole: Injection site symptoms, namely, pain, warmth, burning; localized burning sensation, substernal chest pain, fever, weakness, generalized coldness, localized edema, tiredness, chest tightness, regional lymphangitis, anaphylactoid reactions (characterized by cardiovascular, respiratory and cutaneous symptoms).

Cardiovascular: Hypotension, vasodilation, pallor, non-specific ECG changes, angina pectoris, phlebitis.

Digestive: Gastrointestinal distress, stomach pain, teeth pain, increased salivation.

Nervous System: Agitation, thirst, convulsions (including grand mal).

Respiratory System: Throat irritation, rhinorrhea, sneezing, dyspnea, wheezing, laryngismus, cough.

Skin: Rash, sweating, pruritus, urticaria (hives).

Special Senses: Tinnitus, conjunctivitis, visual field defect, taste abnormality, dry mouth, lacrimation disorder (tearing), eye irritation.

Laboratory: Transient elevation of serum transaminases.

The following other adverse events were reported. A causal relationship has neither been established nor refuted.

Body as a Whole: Back pain, pain, generalized warmth.

Cardiovascular: Hypertension, tachycardia, migraine, syncope, death related to myocardial infarction or other undetermined causes.

Digestive: Constipation, diarrhea.

Nervous System: Anxiety, anorexia, nystagmus, drowsiness, diplopia, stupor.

Skin: Facial edema, erythema multiforme, epidermal necrolysis.

Special Senses: Eye pain, ear pain.

Data from foreign studies did not reveal any additional adverse experiences.

OVERDOSAGE

The LD_{50} of intravenously administered gadopentetate dimeglumine injection in mice is 5-12.5 mmol/kg and in rats it is 10-15 mmol/kg. The LD_{50} of intravenously administered MAGNEVIST® Injection in dogs is greater than 6 mmol/kg.

Clinical consequences of overdose with MAGNEVIST® Injection have not been reported.

DOSAGE AND ADMINISTRATION

The recommended dosage of MAGNEVIST® Injection is 0.2 mL/kg (0.1 mmol/kg), administered intravenously, at a rate not to exceed 10 mL per minute. More rapid injection rates may be associated with nausea. The maximum total dose is 20 mL. Any unused portion must be discarded.

DOSAGE CHART

Body Weight (kg)	Dose in mL	Approx Duration of Injection in Seconds
10	2.0	20
20	4.0	30
30	6.0	40
40	8.0	50
50	10.0	60
60	12.0	70
70	14.0	80
80	16.0	95
90	18.0	110
100	20.0	120

To ensure complete injection of the contrast medium, the injection should be followed by a 5-mL normal saline flush. The imaging procedure should be completed within 1 hour of injection of MAGNEVIST® Injection.

Parenteral products should be inspected visually for particulate matter and discoloration prior to administration, whenever solution and container permit.

For full prescribing information, see package insert.

Caution: Federal Law Prohibits Dispensing Without Prescription.

Monozygotic Twins With Seizures

Shared Characteristics

Rosalind A. Segal, MD, PhD; Catherine Chapman, MD; John Barlow, MD†

• Eleven sets of monozygotic twins with idiopathic seizure disorders seen at Children's Hospital, Boston, Mass, were reviewed. Nine twin pairs were concordant for seizures. A marked correlation in the precise timing of onset of seizures was found; three sets of twins had their first clinical seizures within a 24-hour period of one another. The clinical features of the seizures and the electroencephalographic patterns, including the location of focal discharges, were strikingly similar in the twin pairs. The significance of these findings in suggesting aberrant processes that may contribute to epileptic syndromes is discussed.

(*Arch Neurol.* 1991;48:1041-1045)

Monozygotic twins with epilepsy provide an opportunity to delineate the genetically determined features of a seizure disorder. Lennox[1] and others[2-4] have previously shown that there is a high degree of concordance in the incidence of epilepsy in monozygotic twins; this suggests that genetic factors are often responsible for an idiopathic seizure disorder. The characteristics of epilepsy that are inherited can also be delineated by investigating monozygotic twins.

The electroencephalographic (EEG) patterns of twins have been compared; the striking similarities seen in monozygotic twins with primary generalized seizures imply that certain characteristic patterns are inherited. Gedda and Tatarelli[2] and Vercelleto and Courjon[4] have noted the frequent correlation in the time of onset of clinical seizures in sets of monozygotic twins. In this article, we present 11 sets of monozygotic twins with idiopathic seizure disorders of varying severity. The concordance of the clinical seizure manifestations, the EEG patterns, and, most strikingly, the timing of onset of the first clinical seizure implicate genetic determinants in these characteristics for both focal and generalized idiopathic epilepsy.

PATIENTS AND METHODS

Members of the Department of Neurology at Children's Hospital, Boston, Mass, were asked to submit names of monozygotic twins, one or both of whom had been seen in the previous 15 years for idiopathic seizures. Any patients with seizures due to tumor, hemorrhage, known trauma, or with febrile seizures only were excluded from this study. All patients had been evaluated at Children's Hospital by a staff neurologist. The charts, and, when possible, the EEGs and imaging studies were reviewed by us. Monozygosity was assessed based on the clinical appearance of the twins. The EEGs were performed and reviewed for asymptomatic twins without charge specifically for this study.

RESULTS

Eleven sets of monozygotic twins seen at Children's Hospital between 1974 and 1989 were evaluated. All these represent children with idiopathic epilepsy. The data are summarized in Tables 1 and 2. As shown in Table 1, nine (82%) of the twins were concordant for seizures. Most impressively, the time of onset of seizure disorders was similar in the twins. Three sets of twins (30%) had their first seizure within 24 hours of one another (pairs 1, 2, and 3). Details of these three instances of synchronous onset are provided below. A fourth family, consisting of a set of triplets, two monozygotic twins with epilepsy of near synchronous onset, and a dizygotic triplet with no seizure history, is also described in further detail below. The concordance in time of onset of seizure disorders is further emphasized by the fact that the mean interval between the onset of seizures in cotwins was less than 3 months in the eight cases that can be analyzed (the twins discordant for seizures, pairs 7 and 10 and pair 5, where age of onset was not known, are excluded from this calculation).

The clinical characteristics and the EEG patterns of the twins were also similar, both for primary generalized and for partial seizures (Table 2). Both pairs of twins with partial seizures had the same location of focal discharges (pairs 1 and 2). The medication regimens that adequately controlled seizures in the twins were compared as shown in Table 2; in six cases the twins were treated with the same medications. In the two pairs with myoclonic seizures, the cotwins were receiving different anticonvulsants.

Pair 1

These male monozygotic twins were born at 36 weeks' gestation to nonconsanguineous parents of Italian descent. Twin B presented at the age of 8 months, after a seizure in which his eyes deviated to the left, and his left arm extended upward. The following day, twin A had a seizure that was identical in appearance. The twins were afebrile. Both twins were microcephalic and had severe developmental delay. The EEGs of both individuals showed hypsarrhythmia; thus, each twin fulfilled the three criteria for West syndrome.[5]

Reprint requests to the Department of Neurology, Children's Hospital, 300 Longwood Ave, Boston, MA 02115 (Dr Segal).

Computed tomographic scan of the head and magnetic resonance imaging showed mild ventricular dilatation and poor gray-white differentiation.

Both patients were initially treated with adrenocorticotropic hormone and valproate. There was subsequent improvement in clinical seizure incidence, in developmental progression, and in their EEGs. As adrenocorticotropic hormone was tapered, both twins showed a dramatic increase in seizure frequency. The EEGs at that time (age 13 months) showed evidence of a right-sided temporal focus in both twin A and twin B (Fig 1). They were treated with carbamazepine in addition to valproate, with a subsequent clear reduction in seizure frequency. A detailed investigation into a possible metabolic or prenatal infectious explanation for the patients' clinical condition did not reveal any specific cause.

Table 1.—Seizure Onset

Twin Pair	Age of First Seizure	Time Interval Between Cotwins' First Seizures
1	8 mo	<24 h
2	6 y	<24 h
3	3.5 mo	4 h
4	5 y	10 d
5	<1 y	Unknown
6	15 mo; 23 mo	8 mo
7	9 y	Second twin seizure free
8	6 mo; 7 mo	17 d
9	10 y; 11 y	8 mo
10	15 mo	Second twin seizure free
11	9 mo; 10 mo	1 mo

Pair 2

Twins A and B were left- and right-handed 6-year-old girls, respectively, referred to the neurology clinic for evaluation of their seizure disorders. They were born after a full-term uncomplicated pregnancy, delivered to a 23-year-old gravida 1, para 0-2 healthy woman by elective cesarean section. Twin A weighed 2664 g (5 lb/14 oz) and twin B weighed 2920 g (6 lb/7 oz). Both twins had a normal perinatal course, and normal subsequent growth and development. At 6 years of age, twin A fell and began crying. Her mother stated she then became limp, her eyes rolled up, and she had clonic movements of the upper and lower extremities lasting a few minutes. She was brought to a nearby hospital. While the parents were registering, twin B began to sway, then collapsed to the floor, lost consciousness, and had clonic movements of all extremities. The patients were afebrile, and laboratory evaluations, including complete blood cell count and toxic screen, were normal. The EEGs performed the following day revealed left-sided temporal discharges in both girls. Neurologic examination was normal. The girls were subsequently unavailable for follow-up, and so the results of imaging studies and their further clinical course are not known.

Pair 3

These patients were monozygotic twin girls, the 38-week gestation products of an uncomplicated pregnancy to a gravida 2 mother. They were delivered by cesarean section, and had a normal perinatal course. At 3.5 months of age, twin A had a generalized tonic-clonic seizure. A second seizure, 2.5 hours later, was also generalized tonic-clonic activity, with a possible right-side focal onset. Four and a half hours after twin A's first episode, while twin A was being evaluated in the emergency department, twin B had a generalized tonic-clonic seizure. Twin B had a second generalized seizure shortly thereafter. Neither patient was febrile nor was there any evidence of intercurrent illness. Evaluation revealed normal electrolyte concentrations, blood cell count, calcium level, and renal function. The cerebrospinal fluid glucose level, protein concentration, and cell count were all normal. However, both twins had markedly elevated serum alkaline phosphatase levels (3577 and 2400 mU/mL, respectively). The combination of seizures and elevated alkaline phosphatemia suggested the possibility that these girls had a variant of Mabry's syndrome,[6] which has been reported as a familial syndrome of hyperphosphatasia, seizures, and mental retardation. Unlike the family reported by Mabry et al, the twins were intellectually normal. Electroencephalograms and computed

Table 2.—Seizure Characteristics*

Twins	Clinical Seizure Type	EEG	Response to Anticonvulsants
1	Myoclonic/atypical absence	At 8 mo, generalized burst suppression; at 13 mo, right temporal focus	ACTH-I, Valproic acid-IV, Carbamazepine-III
2	Complex partial with secondary generalization	Left temporal discharges	Unknown
3	Generalized tonic-clonic	Both normal	Phenobarbital-I
4	Generalized tonic-clonic and atypical absence	Frequent bursts of irregular spike and wave	Valproic acid-I
5	Myoclonic	Photoparoxysmal response to strobe	Clonazepam-I for twin A; Valproic acid-I for twin B
6	Myoclonic	Multifocal polyspike and wave with photoparoxysmal response to strobe	Clonazepam-I, twin A; Clonazepam + Phenobarbital-I, twin B
7	Tonic—twin A only	Twin A, normal (age 9 y); twin B, bursts of generalized spike and wave (age 9 y)	No treatment
8	Twin B—partial with secondary generalization; twin A—generalized tonic-clonic	Bursts of spike and slow wave	Phenobarbital + Diphenylhydantoin-III
9	Generalized tonic-clonic	Generalized spike and wave with photoparoxysmal response to strobe	Diphenylhydantoin-I
10	Generalized tonic-clonic twin B only	Both normal (twin B at 15 mo, twin A at 3 y)	Phenobarbital-I, twin B; twin A not treated
11	Generalized tonic-clonic	Both normal	Mephobarbital + carbamazepine-I, twin A; II, twin B

*EEG indicates electroencephalogram; I, seizure free with or without aura for 1 year or more; II, no more than one seizure per year; III, worthwhile reduction in seizures (greater than or equal to 90% improved); IV, no worthwhile reduction in seizures; and ACTH, adrenocorticotropic hormone.

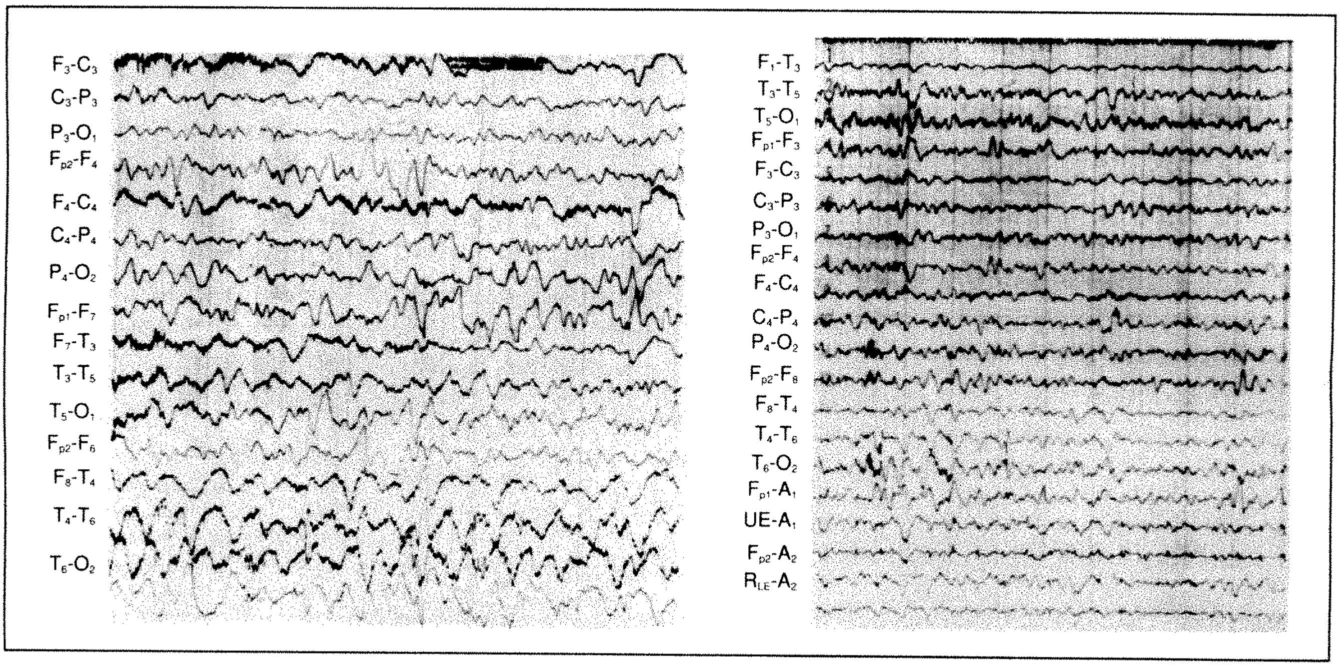

Fig 1.—Portions of electroencephalograms from pair 1. Twin A (left) and twin B (right) at 16 months of age. Both children were receiving valproate alone at the time of these electroencephalograms. A right temporal spike-wave complex with phase reversal over T_6 is demonstrated in both cases.

tomographic scans of the head were normal in both twins. The patients were treated with phenobarbital for the next year, during which time they had no subsequent seizures.

Set 4

These children were products of a 31-week, triple-gestation pregnancy, born to a 30-year-old gravida 1 mother. The triplets consisted of monozygotic twin girls, weighing 1502 (3 lb/5 oz) (twin A), and 1445 g (3 lb/3 oz) (twin B), and a dizygotic triplet boy, weighing 1247 g (2 lb/12 oz). Their neonatal course was notable for the fact that twin B had an aspiration pneumonia at 3 weeks of age. Subsequently, the growth and development of the triplets was within normal limits.

When twin B was 5 years old, she was found on the floor unresponsive, and incontinent of urine. An EEG showed generalized spike and wave activity; ethosuximide was prescribed (Fig 2). Ten days later, twin A was discovered by her sister, lying on the floor with her eyes rolled back, and making pursing movements of her lips. This episode lasted 2 minutes. An EEG also showed bursts of generalized spike and wave activity (Fig 3), and treatment with ethosuximide was started. Both twins were afebrile at the time of the seizures.

Magnetic resonance imaging studies of twin A showed prominent perivascular spaces in deep and subcortical white matter. Images of twin B showed discrete echodense signals in periventricular white matter. The relationship of these nonspecific abnormalities to the twins' generalized seizure disorder is not clear. Both twins had further atypical absence and tonic-clonic seizures. Therefore, treatment with valproate was begun, with subsequent resolution of clinical seizures. The third, dizygotic triplet never had any clinical seizures; an EEG was within normal limits.

COMMENT

The importance of genetic factors in the cause of idiopathic seizures has been recognized as long as convulsions have been viewed as a medical illness.[7] The precise abnormalities that result in genetic seizure disorders are only defined in a very small percentage of cases. One approach to understanding the genetic causes of diverse seizure types is to define the aspects of a seizure disorder that are shared by monozygotic twins with epilepsy. While this does not define precise molecular defects that result in epilepsy, it provides clues as to the aberrant processes that can contribute to this disorder.

The series of monozygotic twins presented here adds to previous surveys of twins with seizures. In this article, 11 sets of monozygotic twins in which one or both twins had nonfebrile, idiopathic seizure(s) were surveyed. In the case of nine sets of twins, both patients had at least one seizure. This very high concordance rate of 82% is similar to previous studies. Furthermore, in pair 7, one of the two instances where one twin has had a seizure and the other has not, the asymptomatic twin had an abnormal EEG, with bursts of generalized spike and wave activity, while the symptomatic twin had a normal EEG. This finding suggests that the "non-epileptic" child shares his twin's propensity for seizures, and that the actual concordance rate is probably greater than 82%.

Studies of monozygotic twins carried out over the last 50 years have shown that 60% to 94% of twins share the propensity for seizures[1-4]; we report a rate of 82%. Since the retrospective study presented here depends on clinicians' memories of twins they have treated, the pairs presented could be biased in favor of twins concordant for seizures. However, the concordance rate found in this study agrees with previous studies that do not suffer from this potential bias.[1-4] This implies that this bias is unlikely to be of major significance. The concordance rate in dizygotic twins was not investigated here, but has been previously shown to be considerably lower, at 23.8% in one study.[3] Set 4, with monozygotic girls, both with seizures, and a dizygotic boy without a seizure disorder demonstrates well the higher concordance in monozygotic twins. The fact that there is such a high rate of concordance in monozygotic twins emphasizes the major role of genetics in idiopathic epilepsy.

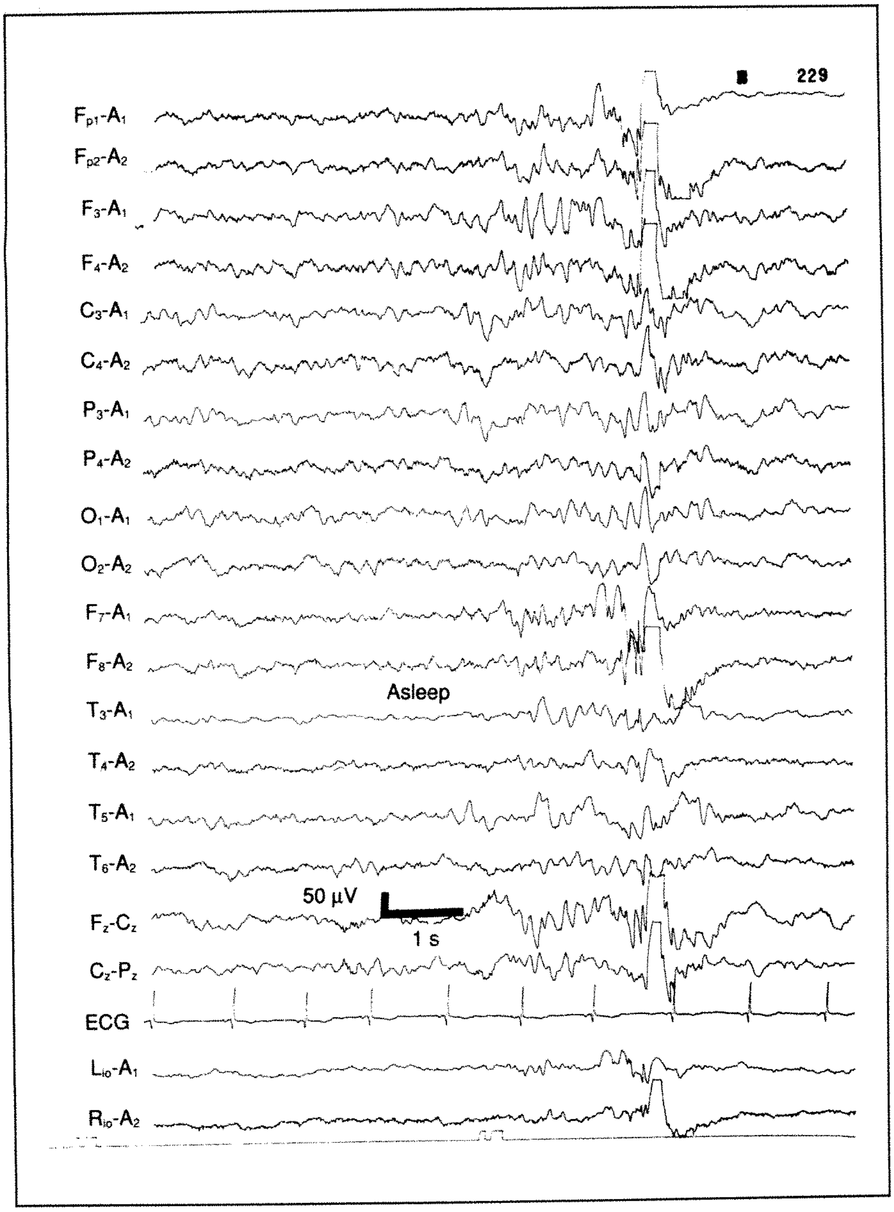

Fig 2.—Portion of electroencephalogram from set 4, twin A, at 5 years of age. Note generalized spike and wave activity. ECG indicates electrocardiogram.

While documenting the high concordance for seizures in monozygotic twins is important for underlining the major role of genetics in idiopathic seizures, an assessment of other features of the twins' seizures may help identify abnormalities that can result in seizures. In our series, the monozygotic twins share not only the propensity for seizures, they also display similar seizure types, and have similar EEGs. In all sets, whether the seizures were focal (ie, pairs 1 and 2) or generalized, the clinical presentations were similar in each set of twins. The EEG patterns, whether generalized or focal, were also strikingly similar. In both of the pairs where there was a focal area of discharge, the location of the focal abnormality was the same (Fig 1).

Previous authors have investigated the similarity between the seizure types and the EEG patterns in epileptic twins. Seizure manifestations are similar in 70% to 100% of twins with primary generalized seizures—whether tonic-clonic, absence, or myoclonic.[1,8] One of the pairs presented here (pair 1) also demonstrates the concordance of seizure type in twins with infantile spasms and West syndrome. There is one previously documented pair of identical twins, both of whom had infantile spasms.[9] Our series of twins further demonstrates that the clinical type of generalized seizure is subject to genetic control.

While genetic factors have been known to be of importance in generalized seizures for some time, the importance of heredity in partial seizures has only been recognized more recently, with evidence of familial clustering of EEG centrotemporal discharges and of Rolandic seizures.[10,11] One study of a single pair of monozygotic twins with partial complex seizures found that the twins shared the seizure manifestations as well as the focal discharges on EEG.[12] Our series provides another case of partial complex seizures in monozygotic twins where the clinical and the electrical abnormalities are strikingly similar (pair 2). An additional pair (pair 1) involves twins with both generalized and partial seizures. In these sets, the clinical manifestations of the partial seizures were similar, and the location of focal discharges on EEGs were the same (Fig 1). This series of twins adds to the growing recognition of the importance of heredity in partial as well as generalized seizures. The fact that the location of abnormal electrical discharges is shared in twins prompts attention to the role of genetics in focal maldevelopment.

Prior studies of twins with seizures have not focused on the response to medications or on the degree of control achieved. In seven cases in this series, seizures were controlled in both twins by the same medication regimen. In the two pairs with myoclonic seizures, pairs 3 and 4, clonazepam was initially used for therapy. In each family, only one twin continued to have seizures, and a second medication was added or substituted for that twin, with subsequent improved control.

The most striking feature in this series of epileptic twins is the frequency with which the time of onset was shared by the twins. In three pairs (1, 2, and 3), the first seizures of the twins were synchronous, occurring within 24 hours of each other. The patients were afebrile at the time of their seizures, so a shared infection is unlikely to explain this timing. Furthermore, for all of the twins, both of whom had seizures, the onset of seizures was within 1 year of each other. The mean time between onset of one and the other twins' seizures was 2.3 months in the eight cases that can be analyzed.

Prior studies of twins with seizures have, in general, not compared the age of onset in twins. Lennox[1] and Vercelletto and Courjon[4] each made note of a case in which twins had onset of seizures within 24 hours of each other. They did not, however, discuss the generality of this synchrony or its significance. In one prior series of 19 monozygotic twins, 11 sets had their first seizures within 1 month of each other.[2] In only one pair

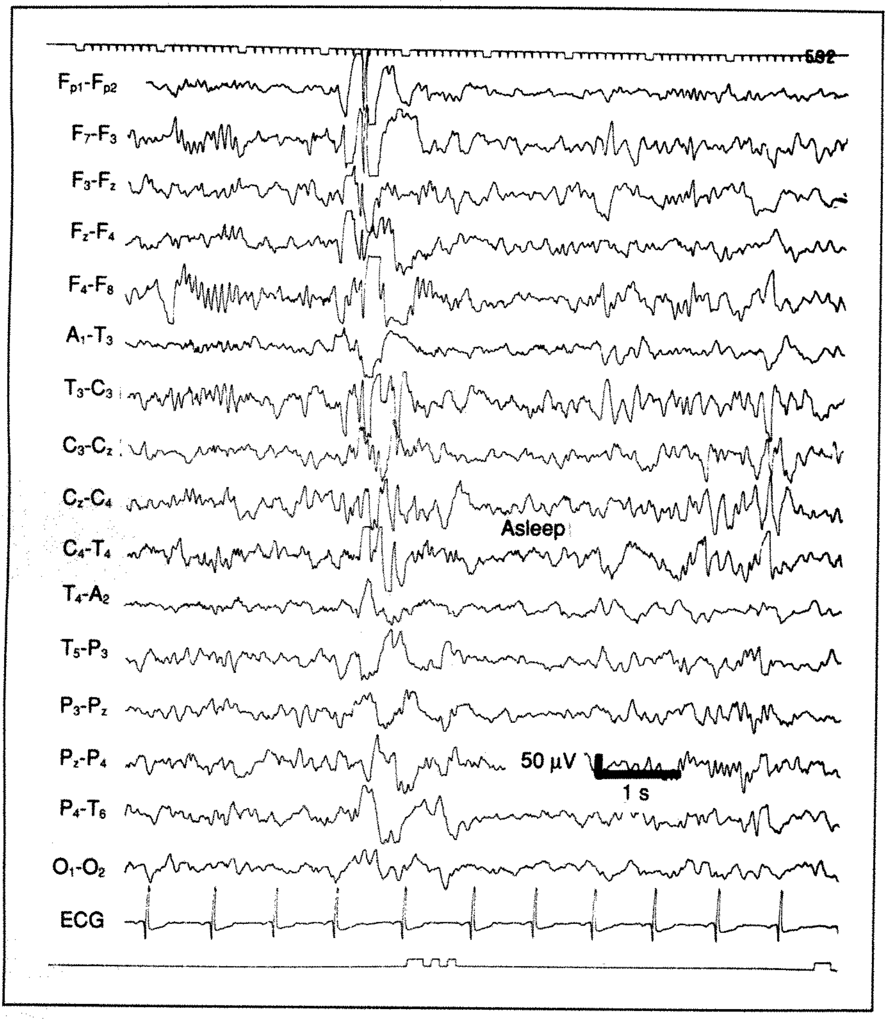

Fig 3.—Portion of electroencephalogram from set 4, twin B, at 5 years of age. Note the generalized spike and wave activity, as in Fig 2. ECG indicates electrocardiogram.

was the first seizure more than 1 year apart; and the mean interval in onset of the cotwins seizures was 6.5 months in the 18 cases of their series that can be analyzed.[2]

The marked synchrony of onset of seizures in monozygous twins suggests that the cause of epilepsy, at least in many cases, is likely to be due to a process that continues in a regulated fashion through postnatal life. Possibilities include myelination, cell death, and synaptic rearrangements. Myelination continues approximately through age 30 years,[13] with myelination of the cortical-connecting fibers a relatively late event. Abnormal myelination could explain either focal or generalized seizures. In pair 1, the abnormal gray-white differentiation seen in imaging studies would be consistent with such an abnormality. Postnatal connections can change through selective neuronal cell death, or through changes in neuronal synapses. Abnormal genetic regulation of either of these two processes could result in the onset of epilepsy at a specific age. Further investigation into genetic control of myelination, cell death, and synaptic reorganization is needed to determine more of the specific abnormalities that can cause epilepsy.

We thank Jane Achenbach-Ng, MD, Charles Barlow, MD, Nancy Canter-Weiner, MD, Gregory Holmes, MD, Jeffrey Macklis, MD, Jeffrey Saver, MD, David Urion, MD, and Lisa Yessayan, MD, for providing us with cases. We thank Gregory Holmes, MD, for providing electroencephalograms of asymptomatic twins. We thank Gregory Holmes, MD, and Joseph Volpe, MD, for their support and their helpful comments on the manuscript.

This article is dedicated to the memory of John Barlow.

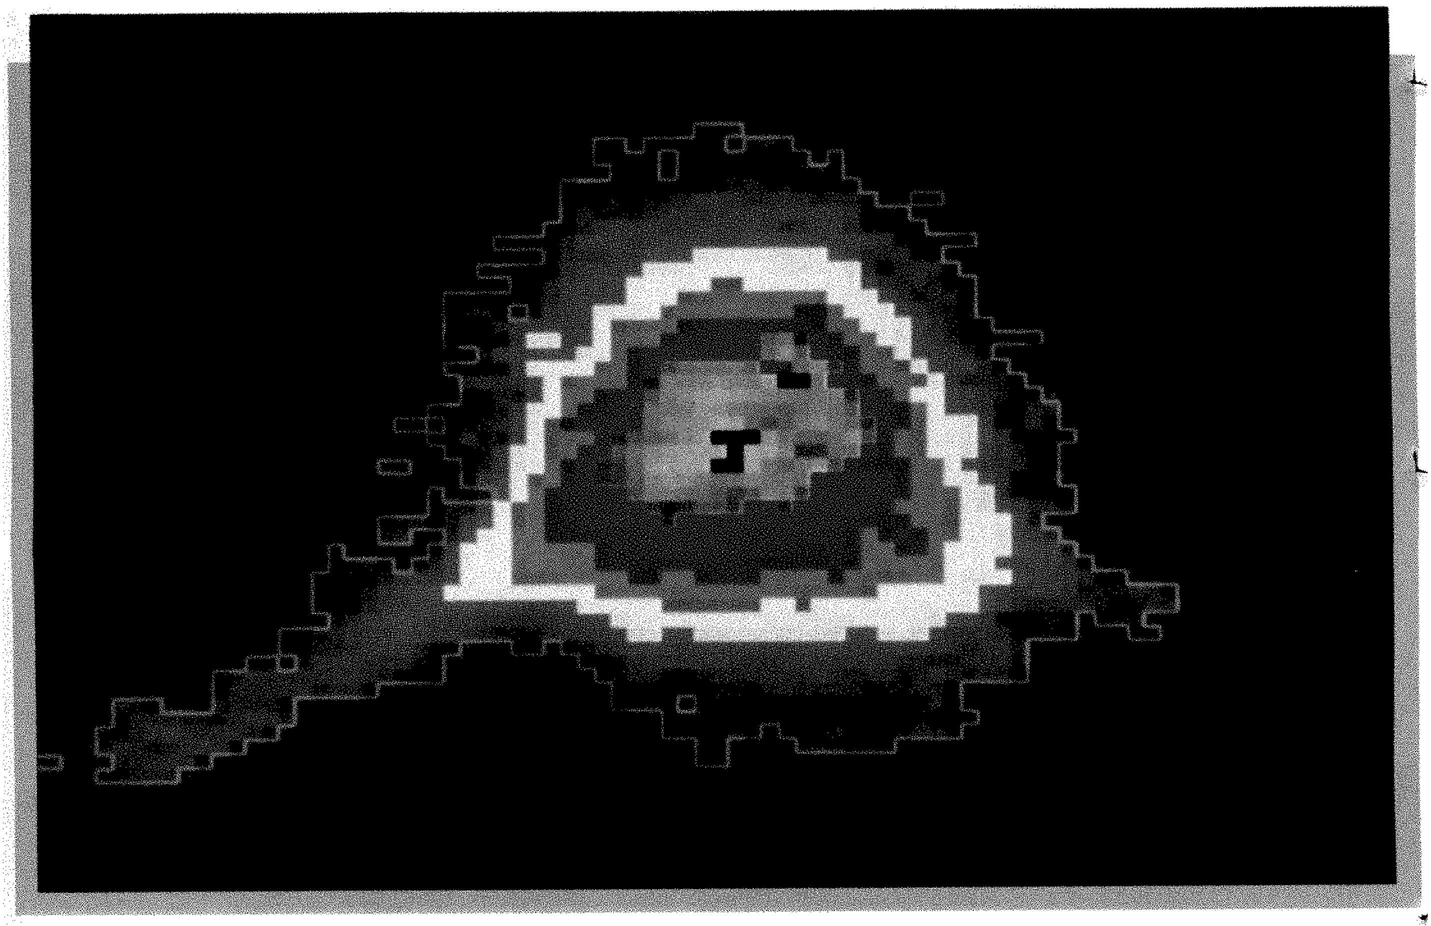
Current hypotheses suggest

Calcium influx is a key component of ischemic injury[1-4]

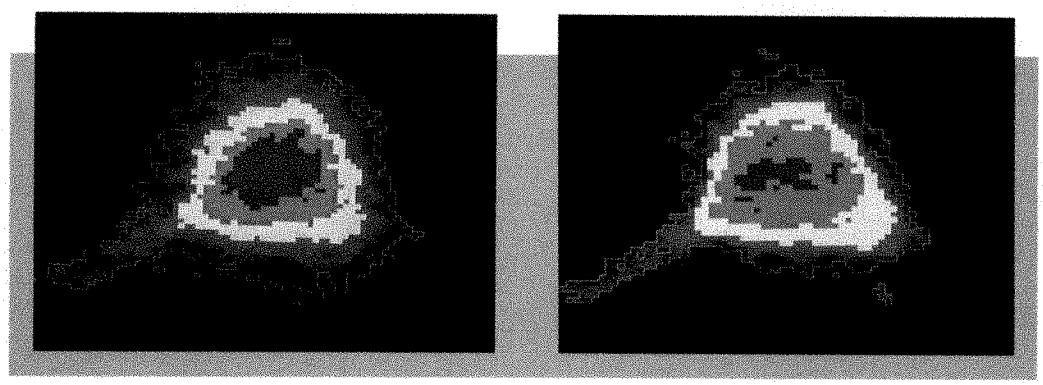


Photomicrograph of depolarized cultured rat hippocampal neuron, showing elevated intracellular calcium. Blue represents lowest and gray represents highest concentration of metabolically active ionized calcium.

Ischemia is associated with calcium influx which activates phospholipases and degrades neuronal cell membranes[2-4]

Cerebroselective calcium channel blockade may protect against ischemic injury

NIMOTOP modulates calcium influx to promote cerebral perfusion and may directly protect neurons[5-7]



Nimodipine-treated cultured rat hippocampal neuron under depolarizing conditions, showing decreased intracellular calcium.

Cultured rat hippocampal neuron showing normal intracellular calcium.[8]

BRIEF SUMMARY
NIMOTOP® (nimodipine/Miles) CAPSULES
For Oral Use

INDICATIONS AND USAGE

Nimotop® (nimodipine) is indicated for the improvement of neurological deficits due to spasm following subarachnoid hemorrhage from ruptured congenital intracranial aneurysms in patients who are in good neurological condition post-ictus (e.g. Hunt and Hess Grades I-III). Oral Nimotop® therapy should begin within 96 hours of the subarachnoid hemorrhage and continue for 21 days.

CONTRAINDICATIONS

None known.

PRECAUTIONS

General: Blood Pressure: Nimodipine has the hemodynamic effects expected of a calcium channel blocker, although they are generally not marked. In patients with subarachnoid hemorrhage given Nimotop® in clinical studies, about 5% were reported to have had lowering of the blood pressure and about 1% left the study because of this (not all could be attributed to nimodipine). Nevertheless, blood pressure should be carefully monitored during treatment with Nimotop® based on its known pharmacology and the known effects of calcium channel blockers.

Hepatic Disease: The metabolism of Nimotop® is decreased in patients with impaired hepatic function. Such patients should have their blood pressure and pulse rate monitored closely and should be given a lower dose (see Dosage and Administration).

Laboratory Test Interactions: None known.

Drug Interaction: It is possible that the cardiovascular action of other calcium channel blockers could be enhanced by the addition of Nimotop®.

In Europe, Nimotop® was observed to occasionally intensify the effect of antihypertensive compounds taken concomitantly by patients suffering from hypertension: this phenomenon was not observed in North American clinical trials.

Carcinogenesis, Mutagenesis, Impairment of Fertility: In a two-year study, higher incidences of adenocarcinoma of the uterus and Leydig-cell adenoma of the testes were observed in rats given a diet containing 1800 ppm nimodipine (equivalent to 91 to 121 mg/kg/day nimodipine) than in placebo controls. The differences were not statistically significant; however, the higher rates were well within historical control range for these tumors in the Wistar strain. Nimodipine was found not to be carcinogenic in a 91-week mouse study but the high dose of 1800 ppm nimodipine-in-feed (546 to 774 mg/kg/day) shortened the life expectancy of the animals. Mutagenic studies, including the Ames, micronucleus and dominant lethal tests were negative.

Nimodipine did not impair the fertility and general reproductive performance of male and female Wistar rats following oral doses of up to 30 mg/kg/day when administered daily for more than 10 weeks in the males and 3 weeks in the females prior to mating and continued to day 7 of pregnancy. This dose in a rat is about 4 times the equivalent clinical dose of 60 mg q4h in a 50 kg patient.

Pregnancy: Pregnancy Category C. Nimodipine has been shown to have a teratogenic effect in Himalayan rabbits. Incidences of malformations and stunted fetuses were increased at oral (by gavage) doses of 1 and 10 mg/kg/day administered from day 6 through day 18 of pregnancy but not at 3.0 mg/kg/day in one of two identical rabbit studies. In the second study an increased incidence of stunted fetuses was seen at 1.0 mg/kg/day but not at higher doses. Nimodipine was embryotoxic, causing resorption and stunted growth of fetuses, in Long Evans rats at 100 mg/kg/day administered by gavage from day 6 through day 15 of pregnancy. In two other rat studies, doses of 30 mg/kg/day nimodipine administered by gavage from day 16 of gestation and continued until sacrifice (day 20 of pregnancy or day 21 post partum) were associated with higher incidences of skeletal variation, stunted fetuses and stillbirths but no malformations. There are no adequate and well controlled studies in pregnant women to directly assess the effect on human fetuses. Nimodipine should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus,

Nursing Mothers: Nimodipine and/or its metabolites have been shown to appear in rat milk at concentrations much higher than in maternal plasma. It is not known whether the drug is excreted in human milk. Because many drugs are excreted in human milk, nursing mothers are advised not to breast feed their babies when taking the drug.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

Adverse experiences were reported by 92 of 823 patients with subarachnoid hemorrhage (11.2%) who were given nimodipine. The most frequently reported adverse experience was decreased blood pressure in 4.4% of these patients. Twenty-nine of 479 (6.1%) placebo treated patients also reported adverse experiences. The events reported with a frequency greater than 1% are displayed below by dose.

DOSE q4h
Number of Patients (%)

	Nimodipine					Placebo
Sign/Symptom	**0.35 mg/kg (n = 82)**	**30 mg (n = 71)**	**60 mg (n = 494)**	**90 mg (n = 172)**	**120 mg (n = 4)**	**(n = 479)**

Acne	0	1 (1.4)	0	0	0	0
Depression	0	1 (1.4)	0	0	0	0

There were no other adverse experiences reported by the patients who were given 0.35 mg/kg q4h, 30 mg q4h or 120 mg q4h. Adverse experiences with an incidence rate of less than 1% in the 60 mg q4h dose group were: hepatitis; itching; gastrointestinal hemorrhage; thrombocytopenia; anemia; palpitations; vomiting; flushing; diaphoresis; wheezing; phenytoin toxicity; lightheadedness; dizziness; rebound vasospasm; jaundice; hypertension; hematoma.

Adverse experiences with an incidence rate less than 1% in the 90 mg q4h dose group were: itching; gastrointestinal hemorrhage; thrombocytopenia; neurological deterioration; vomiting; diaphoresis; congestive heart failure; hyponatremia; decreasing platelet count; disseminated intravascular coagulation; deep vein thrombosis.

As can be seen from the table, side effects that appear related to nimodipine use based on increased incidence with higher dose or a higher rate compared to placebo control, included decreased blood pressure, edema and headaches which are known pharmacologic actions of calcium channel blockers. It must be noted, however, that SAH is frequently accompanied by alterations in consciousness which lead to an under reporting of adverse experiences. Patients who received nimodipine in clinical trials for other indications reported flushing (2.1%), headache (4.1%) and fluid retention (0.3%), typical responses to calcium channel blockers. As a calcium channel blocker, nimodipine may have the potential to exacerbate heart failure in susceptible patients or to interfere with A-V conduction, but these events were not observed.

No clinically significant effects on hematologic factors, renal or hepatic function or carbohydrate metabolism have been causally associated with oral nimodipine. Isolated cases of non-fasting elevated serum glucose levels (0.8%), elevated LDH levels (0.4%), decreased platelet counts (0.3%), elevated alkaline phosphatase levels (0.2%) and elevated SGPT levels (0.2%) have been reported rarely.

OVERDOSAGE

There have been no reports of overdosage from the oral administration of Nimotop®. Symptoms of overdosage would be expected to be related to cardiovascular effects such as excessive peripheral vasodilation with marked systemic hypotension. Clinically significant hypotension due to Nimotop® overdosage may require active cardiovascular support. Norepinephrine or dopamine may be helpful in restoring blood pressure. Since Nimotop® is highly protein-bound, dialysis is not likely to be of benefit.

DOSAGE AND ADMINISTRATION

Nimotop® is given orally in the form of ivory colored, soft gelatin 30 mg capsules for subarachnoid hemorrhage.

The oral dose is 60 mg (two 30 mg capsules) every 4 hours for 21 consecutive days. Oral Nimotop® therapy should commence within 96 hours of the subarachnoid hemorrhage.

If the capsule cannot be swallowed, e.g., at the time of surgery, or if the patient is unconscious, a hole should be made in both ends of the capsule with an 18 gauge needle, and the contents of the capsule extracted into a syringe. The contents should then be emptied into the patient's *in situ* naso-gastric tube and washed down the tube with 30 mL of normal saline (0.9%).

Patients with hepatic failure have substantially reduced clearance and approximately doubled C_{max}. Dosage should be reduced to 30 mg every 4 hours, with close monitoring of blood pressure and heart rate.

Tremor at Onset

Predictor of Cognitive and Motor Outcome in Parkinson's Disease?

Linda A. Hershey, MD, PhD; Brian J. Feldman, MD; Kye Y. Kim, MD; Chris Commichau; David G. Lichter, MD

• We examined 46 male patients with idiopathic Parkinson's disease to see whether tremor at onset was as useful a predictor of benign clinical outcome as tremor predominance after several years. When we compared patients with tremor at onset (n = 27) with those whose disease began with bradykinesia/rigidity (n = 9), or gait disorder (n = 10), we found no significant differences after a mean of 7 years in motor, cognitive, or affective status. Sixteen of the tremor-onset patients continued to have tremor predominance with minimal gait disorder after about 7 years. These tremor-predominant patients had significantly better motor outcome and somewhat better cognitive outcome than either tremor-onset patients who subsequently developed gait disorder (n = 11) or patients without tremor at onset (n = 19). Tremor predominance after several years appears to be a better predictor of a benign clinical course of Parkinson's disease than tremor at onset.

(*Arch Neurol.* 1991;48:1049-1051)

Patients with Parkinson's disease (PD) who continue to have tremor predominance after 2 to 7 years have been found to develop less motor and functional impairment than those with predominance of rigidity, bradykinesia, or gait disorder.[1-5] This finding has been used to argue the possibility of two subtypes of PD, with differences in underlying pathophysiologic features. Huber and others[4] suggested that patients with tremor at onset be compared longitudinally with those whose onset was characterized by rigidity, bradykinesia, or gait disorder.

Several studies[3,4,6,7] have shown that cognitive impairment varies inversely with tremor severity in PD, while others[8,9] have found a positive correlation. In one large cohort of patients with early PD, no significant difference was found when cognitive performance of the tremor-predominant group was compared with that of the group with postural instability and gait disorder.[5]

Depression is seen in 10% to 70% of PD patients,[10] and it is positively correlated with motor dysfunction, according to some.[11-14] Others,[4,15-19] however, report the lack of correlation between motor and affective dysfunction in PD.

We examined a broad spectrum of PD patients to see whether tremor at onset was as accurate a predictor of good motor outcome as was tremor predominance after several years. We also assessed the cognitive and affective status of these patients, looking for correlations with tremor predominance.

PATIENTS AND METHODS

Patients

Forty-six men over the age of 40 years with idiopathic PD gave written informed consent to participate in this study soon after they were enrolled in a newly established Movement Disorders Clinic at the Buffalo (NY) Department of Veterans Affairs Medical Center. The diagnosis of PD was based on the presence of at least two cardinal signs, according to the criteria of Hoehn and Yahr.[2] At the time of enrollment, we inquired about the age and primary symptom at onset of PD (tremor, rigidity, bradykinesia, or gait disorder). Excluded were patients with (1) exposure to neuroleptics, reserpine, or 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP); (2) a history of encephalitis; (3) signs of progressive supranuclear palsy, Shy-Drager syndrome, olivopontocerebellar atrophy, or stroke; (4) psychosis or dementia prior to onset of PD; or (5) alcohol/drug abuse within the last 5 years.

Treatment

Thirty-seven of the 46 patients were being treated with carbidopa/levodopa, with or without adjunctive therapies such as bromocriptine (n = 21), amantadine hydrochloride (n = 19), trihexyphenidyl hydrochloride (n = 3), or diphenhydramine hydrochloride (n = 2). Six patients received amantadine without levodopa; one had diphenhydramine alone and two did not yet need pharmacotherapy. Two patients had had essential tremor for several years prior to the onset of PD and were receiving primidone in addition to carbidopa/levodopa and bromocriptine or amantadine. One patient was treated with a standard therapeutic dose of amitriptyline for his depression (150 mg/d), while three others received lower doses (50 mg/d). Patients were stabilized using doses of antiparkinsonian therapy that seemed optimal for them for at least 1 month prior to enrollment into this study.

Clinical Assessment

Severity of parkinsonism was graded by the 0 through 5 functional staging system of Hoehn and Yahr[2] and a modified Columbia scale,[20] where each of 12 parkinsonian signs (dysarthria, facial masking, rest tremor, postural tremor, rigidity, bradykinesia, finger-tap frequency, foot-tap frequency, rising from a chair, posture, postural instability, and gait disorder) was rated on a 0-through-4-point scale. Ability to perform activities of daily living was assessed by asking the patient's spouse or next of kin the 10 questions of the Barthel Index.[21] Total scores on this measure varied from 0 (totally dependent) to 100 (totally independent).

Cognitive Assessment

The presence of dementia was determined using the *Diagnostic and Statistical Manual of Mental Disorders, Third Edition, Revised* (*DSM-III-R*) criteria.[22] Severity of cognitive dysfunction was estimated using the 30-question Cognitive Capacity Screening Examination of Jacobs and others,[23] on which the potential range of scores was 0 (no correct answers) to 30 (perfect score). A Cognitive Capacity Screening Examination score of 20 or less has been correlated with the presence of dementia by *DSM-III* criteria in PD patients as well as in those with other neurodegenerative disorders.[24] Severity of cognitive impairment was also assessed by interviewing the patients' surrogate with the 10-question Functional Activities Questionnaire of Pfeffer and others,[25] on which the potential range of scores was 0 (no functional impairment) to 30 (total dependence on others). On this scale, the cut-off score for Parkinson's dementia according to *DSM-III* criteria is 12 or more.[26]

Affective Assessment

The presence of major depression or dysthymia was determined using *DSM-III-R* criteria.[22] Severity of depression was graded on a scale of 0 (no affective symptoms) to 62 (most severe symptoms), using the 21-item Hamilton Rating Scale for Depression.[27] Patients rated the severity of their own affective symptoms on the 20-question Zung Self-Rating Scale,[28] on which raw scores ranged from 20 (no affective symptoms) to 80 (most severe symptoms).

Accepted for publication April 4, 1991.

From the Departments of Neurology (Drs Hershey and Lichter) and Psychiatry (Dr Kim), Department of Veterans Affairs Medical Center and State University of New York at Buffalo. Dr Feldman and Mr Commichau were students working in the Neurology Department at the time of this study.

Presented, in part, at the First International Congress of Movement Disorders, Washington, DC, April 25, 1990.

Reprint requests to Department of Neurology, 3495 Bailey Ave, Buffalo, NY 14215 (Dr Hershey).

Statistical Analysis

We used analysis of variance to compare means of continuous variables in the three symptom-onset groups. Comparisons of ordinal data (Hoehn and Yahr stages) from the three groups were performed with the Kruskal-Wallis test. Results in Tables 1 through 4 were expressed as the mean ± 1 SD.

RESULTS

Twenty-seven patients experienced tremor as the earliest symptom of their PD; nine noted rigidity or bradykinesia, and 10 complained of gait disorder at onset. Patients ranged in age from 43 to 77 years (mean age, 68.0 years) at the time of examination, while age at onset ranged from 25 to 75 years (mean age, 59.9 years). Neither age at disease onset nor age at examination differed significantly among the three symptom-onset groups (Table 1).

The groups did not differ with respect to total years of education (mean, 11.8 years; range, 5 to 19 years) or duration of parkinsonism (mean, 8.1 years; range, 1 to 35 years). The range of daily doses of levodopa was from 200 to 1500 mg/d (mean dose, 705 mg/d). There was a trend for the mean daily levodopa dose to be lower in the group with tremor at onset, but between-group differences were not statistically significant (Table 1), neither were there significant differences in mean daily doses of bromocriptine or amantadine.

Patients in this study encompassed a broad spectrum of Hoehn and Yahr stages (mean, 3.0; range, 1 to 4). When motor and functional outcome measures were compared among the three symptom-onset groups, no significant differences were found (Table 2). There were also no significant differences in measures of cognitive and affective status (Table 2). Three patients with tremor at onset met *DSM-III-R* criteria for dementia by the time of enrollment. These three had also developed a significant gait disorder. Two patients whose PD had begun with rigidity and two with gait disorder also met the criteria for dementia.

Bromocriptine dose, mg	10.5 ± 2.7	7.5 ± 3.1	11.4 ± 8.0
Amantadine dose, mg	250 ± 55	225 ± 50	267 ± 52

Patients were regrouped according to historical information about symptoms at onset and objective findings at the time of enrollment. Those with tremor at onset were divided into two groups. One group of 16 patients with tremor at onset still had tremor predominance at the time of examination (gait scores, 0/4 to 1/4). Another group of 11 patients had had tremor at onset, but their gait scores were 2/4 to 3/4 by the time of enrollment. Data from the 19 patients whose disease had begun with rigidity, bradykinesia, or gait disorder were pooled for this comparison (Table 3). These three subgroups did not differ with respect to age at examination, age at onset, years of education, duration of disease, or mean daily doses of antiparkinsonian drugs.

Tremor-onset patients who continued to have tremor predominance after about 7 years had significantly milder motor function than did the others, according to measures such as the Hoehn and Yahr stage, modified Columbia scale, and Barthel Index (Table 4). While no significant differences were found among the three groups in mean Cognitive Capacity Screening Examination scores, patients with tremor predominance had statistically better cognitive function as reflected by Functional Activities scores (Table 4). None of the seven demented patients in this series belonged to the tremor-predominant group. No significant affec-

tive differences were found among these subgroups, according to the Hamilton Rating Scale for Depression and the Zung Self-Rating Scale scores (Table 4). Ten of the 46 patients satisfied the *DSM-III-R* criteria for major depression and four met the criteria for dysthymia.

COMMENT

We found that tremor predominance after about 7 years was a statistically significant predictor of good motor outcome in men with PD, while tremor at onset was not. This finding appeared to be independent of important variables such as age at onset and duration of disease. Tremor predominance after 5 to 7 years has already been shown to be associated with a more benign clinical course, but these studies did not examine symptoms at onset.[1-4] In the DATATOP cohort, tremor predominance after about 2 years was a statistically significant predictor of good motor outcome, even though tremor at onset was not.[5]

According to our data, tremor at onset does not necessarily predict good cognitive outcome, even though tremor predominance after 7 years does. None of our 16 tremor-predominant patients had developed dementia by the time of examination, while three of our tremor-onset patients had. Jankovic and others[5] also reported the lack of correlation between cognitive performance and type of symptoms at onset, although their sample was limited to patients with early PD and excluded those with significant cognitive impairment. Our data also agree with those of Huber and others,[4] who showed a significant correlation between tremor predominance after several years and good cognitive outcome.

Neither tremor at onset nor tremor predominance appeared to be a good predictor of affective outcome in men with PD. We also found no significant correlation between individual measures of motor and affective dysfunction. These observations are consistent with the findings of others,[4,15-19] and they support the hypothesis that there is a pathophysiologic distinction between motor and affective dysfunction in PD.

Anatomical and biochemical heterogeneity in PD has been suggested by various autopsy-based studies.[29,30] Future studies using positron emission tomography may show different patterns of 18-fluorodopa uptake in tremor-onset patients who develop early gait disorder and impairment of cognitive function, compared with those who do not.

We appreciate the funding received by Dr Feldman from the National Institutes of Health, Bethesda, Md (1987 student research fellowship under grant AG000089), and by Mr Commichau from the Neuropharmacology Research Fund of the University at Buffalo (NY) Foundation (student research stipend).

We acknowledge our discussions of the data with Joseph Jankovic, MD, Bradley Truax, MD, and George Paulson, MD.

Tritiated Imipramine Binding

A Peripheral Marker for Serotonin in Parkinson's Disease

Mary Sano, PhD; Michael Stanley, PhD; Arlene Lawton, RN; Lucier Coté, MD; Janet Williams, DSW;
Yaakov Stern, PhD; Karen Marder, MD; Richard Mayeux, MD

• Tritiated imipramine binding in platelets has been used to evaluate serotonin activity in depression in previous studies. This article examined this marker as a possible measure of central nervous system serotonergic activity for depression in patients with Parkinson's disease (PD). The number of binding sites was significantly lower in depressed patients with PD than in a healthy control group. Patients with PD who were not depressed had lower values than the comparison group, but this difference was not significant. We also found a significant correlation between the receptor site values in platelets and cerebrospinal fluid levels of the serotonin metabolite, 5-hydroxyindoleacetic acid ($r = .59$), but this was independent of a diagnosis of depression. Receptor site values were examined to identify appropriate cutoff scores to predict depression in the group of patients with PD. A maximum sensitivity of 50% was achieved with a specificity of 64%. Our results strongly support a generalized alteration in serotonin metabolism in depressed patients with PD, but tritiated imipramine binding in platelets is not a useful diagnostic tool for depression.

(*Arch Neurol.* 1991;48:1052-1054)

The "serotonin hypothesis" of depression in Parkinson's disease (PD) is based on the evidence of a generalized deficiency of serotonin in patients with PD and depression.[1-5] The cerebrospinal fluid (CSF) concentration of the serotonin metabolite, 5-hydroxyindoleacetic acid (5-HIAA), is reduced in patients with PD compared with age-matched controls[1]; levels are even lower in patients with depression.[3] Serotonin also plays a role in depression among individuals who do not have PD, since CSF 5-HIAA levels are lower in depressed patients and in suicide victims.[6,7]

An alternative measure of serotonergic function is tritiated imipramine (^{3}H-imipramine) binding, which measures presynaptic serotonergic receptor sites and has been examined in platelets and brain.[8] Tritiated imipramine binding is lower in the platelets of patients without PD but with depression and is reduced in the brains of depressed patients dying of natural causes or suicide when compared with the brains from those who did not commit suicide.[9] However, others have found no difference in brain or platelet binding between depressed and nondepressed individuals.[10,11]

Correlations between platelet and brain ^{3}H-imipramine binding capacity in animal studies[12] suggest that platelet binding may reflect central nervous system activity. Although Raisman et al[13] found ^{3}H-imipramine binding decreased in the brains of patients with PD (in whom depression was not assessed), earlier reports indicated no difference between individuals with PD and controls.[14] Schneider et al[15] found platelet binding reduced in depressed patients with PD. These conflicting studies used small groups and the diagnostic information concerning depression was not systematically obtained.

This study sought to examine the relationship among depression, CSF 5-HIAA, and ^{3}H-imipramine binding in platelets in patients with PD. Second, it sought to determine whether ^{3}H-imipramine binding in platelets could be a sensitive and specific marker for depression in these patients.

SUBJECTS AND METHODS

Patient Group

Seventy patients with idiopathic PD (mean age, 66.9 ± 9.1 years) participated in this study. The diagnosis of idiopathic PD was defined by the presence of at least two of the following four features: tremor, gait disorder, bradykinesia, and rigidity. Clinical history and other physical symptoms had to be consistent with the idiopathic form of the disease. Patients were excluded if there was evidence implicating another cause for the parkinsonism (eg, phenothiazine exposure or history of encephalitis) and if they had taken any type of antidepressant medication or other psychoactive drug in the last 60 days. However, patients who were taking dopamine agonists or dopamine precursors or anticholinergics for PD were included. The type and dose of medication were recorded.

Control Group

This group consisted of 53 age-matched, healthy elderly individuals (mean age, 66.5 ± 4.7 years) who were accompanying patients to the medical center. This included spouses, companions, and significant others who were not blood relatives of the patient group. These individuals were screened to eliminate central nervous system disease, a history of major depression or other psychiatric illness, or other life-threatening medical illnesses. Individuals were excluded if they had taken antidepressant medication within the past 60 days.

Procedures

After giving informed consent all subjects received the following assessments.

Standardized Medical History.—This included a record of all major medical and neurologic problems, psychiatric treatment history, and current medications. For the patients with PD, a detailed history of the onset of the disease was taken and all treatment regimens were recorded.

PD Severity Ratings.—The Unified Parkinson's Disease Rating Scale[16] was used to assess the presence and severity of motor manifestations. Those items that assess mentation, behavior, and mood (items 1 through 4) were excluded because they were measured with alternate instruments described below. The maximum score possible on the remaining items is 172, with higher scores indicating more severe motor disturbance. The Schwab and England[17] inventory of Activities of Daily Living[17] was used. This inventory rates by percentage the degree of independence in Activities of Daily Living, with 100% referring to total independence and 0% indicating the patient is bedridden with impairment of vegetative functions. The Hoehn and Yahr Scale[18] was also completed. This six-stage index ranges from 0 ("no sign of disease") to 5 ("bedridden or wheelchair bound").

Mental Status.—The modified Mini-Mental State Examination was administered to assess intellectual function. This modifica-

Table 1.—Comparison of Depressed and Nondepressed Patients With Parkinson's Disease (PD) and Healthy Elderly Volunteers*

Group	n	HDRS	Kd	B_{max}
Patients with PD				
Depressed	14	17.4 ± 4.5†	1.6 ± 1.2	740.9 ± 198‡
Nondepressed	56	4.2 ± 3.4	1.6 ± 1.4	862.0 ± 352
Controls	53	4.0 ± 4.2†	2.1 ± 0.8	950.3 ± 255‡

*HDRS indicates Hamilton Depression Rating Scale score; Kd, affinity constant; and B_{max}, number of receptor sites. The total group (patients with PD) was classified as described: depressed, Hamilton Score 12 or more; nondepressed, Hamilton Score less than 12.

†Groups were significantly different ($P < .01$).

‡Groups were significantly different ($P < .05$).

Table 2.—Comparison of Cerebrospinal Fluid (CSF) Metabolites and Binding Measures in Depressed and Nondepressed Patients With Parkinson's Disease*

	Patients With Parkinson's Disease	
	Depressed (n = 8)	Nondepressed (n = 11)
HDRS	16.1 (7.1)†	5.8 (3.6)†
CSF 5-HIAA	14.2 (6.4)	18.8 (6.8)
CSF HVA	52.7 (34.3)	30.5 (12.1)
Kd	1.2 (0.72)	1.5 (0.72)
B_{max}	826.9 (253)	904.2 (384)

*HDRS indicates Hamilton Depression Rating Scale; 5-HIAA, 5-hydroxyindoleacetic acid; HVA, homovanillic acid; Kd, affinity constant; and B_{max}, number of receptor sites. Numbers in parentheses are SDs.

†Groups are significantly different ($P < .01$).

tion of the procedure described by Folstein et al[19] includes additional items that measure naming, language, and attention and has a maximum score of 57. The mean modified Mini-Mental State score for healthy elderly individuals is 52.5 (±4.3).[20]

Psychiatric Evaluation.—A standardized semistructured interview for the Hamilton Depression Rating Scale (HDRS)[21] was administered. Based on previous findings,[1,2] those patients with HDRS scores greater than 12 were classified as clinically depressed.

^{3}H-Imipramine Binding.—Binding of ^{3}H-imipramine in platelets was determined using the method described by Briley et al[22] and modified by Asarch et al.[23]

CSF Studies.—Nineteen of the 70 patients with PD participated in an extended study of biogenic amine metabolites in CSF. These patients were selected because they had cognitive or affective complaints and were admitted to the General Clinical Research Center to complete all assessments. In addition to the HDRS, psychiatric diagnoses for depression were made according to the criteria of the *Diagnostic and Statistical Manual, Revised Third Edition,*[24] using the Structured Clinical Interview[25] completed by a trained interviewer with the patient (and an informant when available).

Lumbar puncture for CSF studies was performed after 18 hours of bed rest. Twenty milliliters of CSF was obtained for biochemical analysis. High-pressure liquid chromatography with amperometric detection was used to measure 5-HIAA and homovanillic acid by a method previously described.[1]

Data Analysis

For ^{3}H-imipramine–binding studies, Scatchard analysis was used to determine the number of receptor sites (B_{max}) and the affinity constant (Kd)[26] for each subject. Tritiated imipramine–binding results were correlated with demographic and disease severity variables. Group mean comparisons were used to examine differences in binding measures between controls and patients. Pearson correlations were used to examine the association between CSF 5-HIAA measures and platelet binding measures. Nonparametric techniques were used to examine the sensitivity and specificity[27] of platelet binding for assessment of depression in PD.

RESULTS

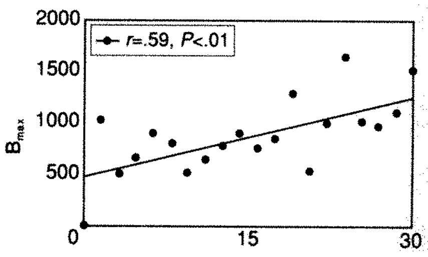
Tritiated imipramine–binding measures for the PD group and the control group were initially compared using a *t* test. This comparison yielded a significant difference between the two groups ($P \leq .05$). Patients with PD were then classified as depressed, using an HDRS score of 12 or greater for depression, or not depressed. The ^{3}H-imipramine–binding measures for the two PD groups and the control group are given in Table 1. An analysis of variance of the B_{max} values yielded a significant F test ($P < .05$) for the comparison of depressed patients with PD, nondepressed patients with PD, and the control group. Post hoc analysis demonstrated significantly lower B_{max} values in the depressed patients with PD than in the controls. The group mean value for the nondepressed patients with PD fell between the other two groups, but was not significantly different from either. Based on effect size reported by Schneider et al,[15] this study had sufficient group size to achieve 65% power for detecting such a difference at the .05 level of significance.

^{3}H-Imipramine–Binding and Disease Severity Measures

The mean duration of illness in the PD group was 8.6 (±2.2) years and the mean Unified Parkinson's Disease Rating Scale score was 41.8 (±26.1). The mean Hoehn and Yahr rating in the PD group was 2.7 (±.79), with 39.1% receiving a score of 1 or 2 (mild disease), 48.4% receiving a score of 3 (moderate severity), and 12.5% receiving a score of 4 or 5 (marked severity). The mean Schwab and England rating was 68.3% (±24.1%) with 23.8% of the patients experiencing serious disability, scoring below 50%. None of these measures were significantly correlated with B_{max} or Kd values.

The mean modified Mini-Mental State score in the PD group was 44.7 (±11.5). This is significantly lower ($P < .05$) than the mean for the control group (52.3 ± 3.4). However, no significant correlation was noted between this measure and B_{max} or Kd values.

Fifty-five (78.6%) patients were taking parkinsonian medication. The correlation between the dose of medication and the B_{max} was not significant ($r = -.2$).



Relationship between the amount of 5-hydroxyindoleacetic acid (5-HIAA) in cerebrospinal fluid (CSF) and the number of tritiated imipramine binding sites in platelets of patients with Parkinson's disease. B_{max} indicates number of receptor sites.

^{3}H-Imipramine–Binding and CSF Measures

Eight (42%) of the 19 patients who had lumbar punctures for the CSF studies were diagnosed as having major depression or dysthymia. They had a mean HDRS score of 16.1 ± 7.1, which represents depression of mild to moderate severity, compared with a mean HDRS score of 5.8 ± 3.6 in the nondepressed patients ($P < .05$). The CSF 5-HIAA and the ^{3}H-imipramine binding values for these patients are given in Table 2. A significant correlation was noted between B_{max} values and CSF 5-HIAA ($r = .59$; $P < .01$) (Figure) but not CSF homovanillic acid ($r = .39$; $P > .1$). The Kd values did not correlate with either CSF metabolite measure.

The mean CSF 5-HIAA level in the depressed group was lower than in the nondepressed group (14.2 ± 6.4 vs 18.8 ± 6.8 ng/mL). This difference was not statistically significant, perhaps due to our small sample size. Based on our previous work,[1] it was estimated that this study yielded low power for this comparison (0.25).

Sensitivity and Specificity of ^{3}H-Imipramine Binding for Depression in PD

The sensitivity and specificity of ^{3}H-imipramine binding to detect depression in PD was examined. A B_{max} cutoff value of 800 correctly classified the maximum number of patients; 37 (53%) of the 70 patients with PD were correctly identified as depressed or not depressed. This value yielded a specificity of 64% and a sensitivity of 50% for depression among the PD group.

COMMENT

This study further supports an alteration in serotonin in PD. First, ^{3}H-imipramine binding in platelets is reduced in patients with PD. A closer examination of these patients demonstrates that patients with depression and PD have significantly fewer binding sites than controls. Patients with PD who were not depressed had BB_{max} values that fell between the controls and the depressed group, although they were not significantly different. Second, platelet binding values significantly correlate with CSF 5-HIAA levels, suggesting that this peripheral measure may reflect central serotonergic activity. Together, these results provide additional evidence for a generalized serotonergic abnormality that may be associated with depression in PD.

The binding values in this study were similar to those reported by Suranyi-Cadotte et al,[14] who found no difference between patients with PD and a comparison group. However, the sample size was much smaller in their study. Schneider and coworkers[15] found a 22% decrease in ^{3}H-imipramine platelet binding in subjects with PD compared with controls. Four of the nine patients with PD had either major depression or dysthymic disorder that may have contributed to the reported difference, although this was not systematically examined. This study demonstrated a 10.9% difference in B_{max} values with a large group size.

This work represents the first report of a correlation between CSF and platelet measures of serotonergic activity. It is usually assumed that CSF markers reflect only nonspecific changes in brain chemistry, but in suicide victims there is a correlation between CSF 5-HIAA and ^{3}H-imipramine–binding sites in the frontal cortex.[28] In depressed patients with PD, Mayberg et al[29] found lowered metabolism in the caudate and in the inferior orbital-frontal cortex, where a serotonergic mechanism for this frontal hypometabolism has been postulated previously.[30] Significant loss of large neurons in the ascending serotonergic pathway of the dorsal raphe nucleus and decreased serotonin concentrations in the projection areas in the frontal cortex have also been reported in patients with PD.[31]

Although pervasive, the serotonergic deficit may not parallel deterioration of the dopamine system. Our previous work indicates no correlation between CSF 5-HIAA and variables associated with disease severity such as age, motor manifestation, or the use of dopamine precursors or agonists.[3] Similarly, this study found no association between these variables and ^{3}H-imipramine–binding measures.

A peripheral marker for depression in PD would be useful because symptoms of depression and PD may overlap. When a B_{max} value was chosen to provide maximum correct classification of depression among patients with PD, the specificity and sensitivity of the measure were too low to be useful as a screen. Despite this, the decrease in B_{max} in depressed patients with PD and the correlation between CSF and platelet measures support a major alteration in serotonergic metabolism in PD that may explain some of the behavioral manifestations of PD.

This work was supported by federal grant AG02802 and by The Parkinson's Disease Foundation. Dr Sano is a Herbert Irving Assistant Professor in Neurology, Columbia University, College of Physicians and Surgeons, New York.

Now even more "essential"

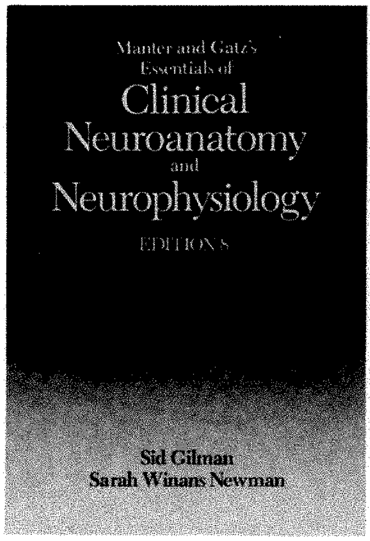
Manter and Gatz's Essentials of Clinical Neuroanatomy and Neurophysiology has proven essential for thousands of medical students, graduate students in the neurosciences, and residents in neurology, neurosurgery and psychiatry. Now available in the new 8th edition, this classic continues to set the standard. Dr. Sid Gilman, an authority in neurophysiology and clinical neurology, and Dr. Sarah Winans Newman, an authority in neuroanatomy, have revised Essentials of Clinical Neuroanatomy and Neurophysiology to fit the changing needs of today's student of the nervous system.

Totally updated to reflect the most recent developments in neuroanatomy, neurophysiology, neuropharmacology, and clinical neurology, this text systematically points out the clinical relevance of the major anatomic structures of the nervous system.

Several new illustrations have refined the anatomic presentation and an expanded index enhances its use as a reference source. Also added are chapters on *The Physiology of Nerve Cells* and *The Blood Supply to the Brain*.

Another new chapter, ***Clinical Evaluation of Patients with Neurologic Disorders***, provides a detailed guide to the neurologic history and examination. This chapter will be especially helpful to those initially approaching patients with neurologic disorders and a refresher to those desiring a review of this topic.

Essentials of Clinical Neuroanatomy and Neurophysiology is helpful for board review at several levels. The comprehensive yet concise and clearly presented information on this subject area lends itself well to review purposes for medical students, graduate students, and clinicians approaching board examinations. Few have gotten through without it!



NEW 8TH EDITION

By Sid Gilman, MD, Professor and Chairman, Department of Neurology; and Sarah Winans Newman, PhD, Professor, Department of Anatomy and Cell Biology; both of the University of Michigan Medical School, Ann Arbor, Michigan.

About 350 pp. Illustd. Soft cover. Ready November 1991. About $21.95.

KEY FEATURES

- Three new chapters—Clinical Evaluation of Patients with Neurologic Disorders, The Physiology of Nerve Cells, and The Blood Supply to the Brain.
- Systematically presents the clinical relevance of the major anatomic structures of the nervous system.
- Reflects the most recent developments in neuroanatomy, neurophysiology, neuropharmacology, and clinical neurology.

TABLE OF CONTENTS

I. Basic Principles
1. Introduction to the Nervous System. 2. The Physiology of Nerve Cells.

II. The Peripheral Nervous System
3. The Spinal Nerves. 4. Spinal Reflexes and Muscle Tone. 5. The Autonomic Nervous System.

III. Ascending and Descending Pathways
6. Pain and Temperature. 7. Proprioception and Tactile Discrimination. 8. Touch. 9. The Descending Pathways. 10. Lesions of the Peripheral Nerves, Spinal Roots, and Spinal Cord.

IV. Brain Stem and Cerebellum
11. Anatomy of the Brain Stem: Medulla, Pons, and Midbrain Medulla. 12. The Cranial Nerves. 13. Cranial Nerves of the Medulla. 14. Cranial Nerves of the Pons and Midbrain. 15. Lesions of the Brain Stem. 16. Hearing. 17. The Vestibular System. 18. The Cerebellum.

V. Higher Levels of the Nervous System
19. The Basal Ganglia and Related Structures. 20. Vision. 21. Optic Reflexes. 22. The Thalamus. 23. The Hypothalamus and Limbic System. 24. The Rhinencephalon and Olfactory Reflexes. 25. The Cerebral Cortex. 26. Chemical Neuroanatomy.

VI. Circulation of Blood and Cerebrospinal Fluid
27. Cerebral Arteries. 28. The Cerebrospinal Fluid.

VII. Approaches to Patients with Neurologic Symptoms
29. Clinical Evaluation of Patients with Neurologic Disorders. 30. Neurologic Diagnostic Tests.

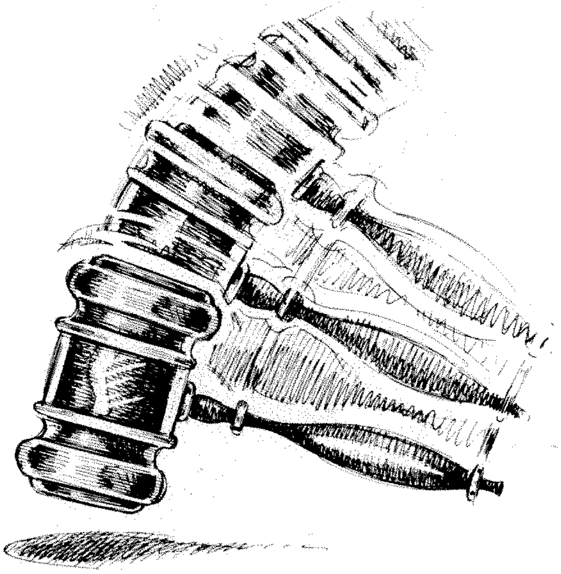
F.A. DAVIS

Doctor, Guilty or Innocent?



Collective action by independently practicing physicians can violate U.S. antitrust laws, and physicians must proceed *very* cautiously.

Case in point:

Have you ever discussed your fees with another physician? Or shared your feelings about an HMO or PPO plan with other MDs in town? Unless the doctors you talked to were your partners, you may have violated U.S. antitrust laws and could face criminal prosecution. If found guilty of price fixing or group boycott, you could be fined, sentenced and stripped of your license.

This may be the most important book you'll ever read:

Collective Negotiation and Antitrust
A Guide for Physicians

The American Medical Association, Office of the General Counsel, has published this book to help you avoid antitrust pitfalls and improve your ability to bargain effectively with payors.

To Order, Call Today: 1-800-621-8335

Price: $5.00 (AMA Members)
$7.50 (Non-members)

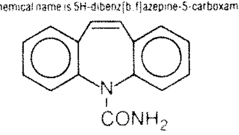
> WARNING
>
> APLASTIC ANEMIA AND AGRANULOCYTOSIS HAVE BEEN REPORTED IN ASSOCIATION WITH THE USE OF TEGRETOL. DATA FROM A POPULATION-BASED CASE CONTROL STUDY DEMONSTRATE THAT THE RISK OF DEVELOPING THESE REACTIONS IS 5-8 TIMES GREATER THAN IN THE GENERAL POPULATION. HOWEVER, THE OVERALL RISK OF THESE REACTIONS IN THE UNTREATED GENERAL POPULATION IS LOW, APPROXIMATELY SIX PATIENTS PER ONE MILLION POPULATION PER YEAR FOR AGRANULOCYTOSIS AND TWO PATIENTS PER ONE MILLION POPULATION PER YEAR FOR APLASTIC ANEMIA.
>
> ALTHOUGH REPORTS OF TRANSIENT OR PERSISTENT DECREASED PLATELET OR WHITE BLOOD CELL COUNTS ARE NOT UNCOMMON IN ASSOCIATION WITH THE USE OF TEGRETOL, DATA ARE NOT AVAILABLE TO ESTIMATE ACCURATELY THEIR INCIDENCE OR OUTCOME. HOWEVER, THE VAST MAJORITY OF THE CASES OF LEUKOPENIA HAVE NOT PROGRESSED TO THE MORE SERIOUS CONDITIONS OF APLASTIC ANEMIA OR AGRANULOCYTOSIS.
>
> BECAUSE OF THE VERY LOW INCIDENCE OF AGRANULOCYTOSIS AND APLASTIC ANEMIA, THE VAST MAJORITY OF MINOR HEMATOLOGIC CHANGES OBSERVED IN MONITORING OF PATIENTS ON TEGRETOL ARE UNLIKELY TO SIGNAL THE OCCURRENCE OF EITHER ABNORMALITY. NONETHELESS, COMPLETE PRETREATMENT HEMATOLOGICAL TESTING SHOULD BE OBTAINED AS A BASELINE. IF A PATIENT IN THE COURSE OF TREATMENT EXHIBITS LOW OR DECREASED WHITE BLOOD CELL OR PLATELET COUNTS, THE PATIENT SHOULD BE MONITORED CLOSELY. DISCONTINUATION OF THE DRUG SHOULD BE CONSIDERED IF ANY EVIDENCE OF SIGNIFICANT BONE MARROW DEPRESSION DEVELOPS.

Before prescribing Tegretol, the physician should be thoroughly familiar with the details of this prescribing information, particularly regarding use with other drugs, especially those which accentuate toxicity potential.

DESCRIPTION

Tegretol, carbamazepine USP, is an anticonvulsant and specific analgesic for trigeminal neuralgia, available as chewable tablets of 100 mg and tablets of 200 mg for oral administration. Its chemical name is 5H-dibenz[b,f]azepine-5-carboxamide, and its structural formula is



Carbamazepine USP is a white to off-white powder, practically insoluble in water and soluble in alcohol and in acetone. Its molecular weight is 236.27.

Inactive Ingredients. Colloidal silicon dioxide, FD&C Red No. 3 (chewable tablets only), FD&C Red No. 40 (200-mg tablets only), flavoring (chewable tablets only), gelatin, glycerin, magnesium stearate, sodium starch glycolate (chewable tablets only), starch, stearic acid, and sucrose (chewable tablets only).

CLINICAL PHARMACOLOGY

In controlled clinical trials, Tegretol has been shown to be effective in the treatment of psychomotor and grand mal seizures, as well as trigeminal neuralgia.

It has demonstrated anticonvulsant properties in rats and mice with electrically and chemically induced seizures. It appears to act by reducing polysynaptic responses and blocking the posttetanic potentiation. Tegretol greatly reduces or abolishes pain induced by stimulation of the infraorbital nerve in cats and rats. It depresses thalamic potential and bulbar and polysynaptic reflexes, including the linguomandibular reflex in cats. Tegretol is chemically unrelated to other anticonvulsants or other drugs used to control the pain of trigeminal neuralgia. The mechanism of action remains unknown.

Tegretol tablets are adequately absorbed after oral administration at a slower rate than a solution, thus avoiding undesirably high peak concentrations. Tegretol chewable tablets may produce higher peak levels than the same dose given as regular tablets. Tegretol in blood is 76% bound to plasma proteins. Plasma levels of Tegretol are variable and may range from 0.5-25 μg/ml, with no apparent relationship to the daily intake of the drug. Usual adult therapeutic levels are between 4 and 12 μg/ml. Following oral administration, serum levels peak at 4 to 5 hours. The CSF/serum ratio is 0.22, similar to the 22% unbound Tegretol in serum. Because Tegretol may induce its own metabolism, the half-life is also variable. Initial half-life values range from 25-65 hours, with 12-17 hours on repeated doses. Tegretol is metabolized in the liver. After oral administration of 14C-carbamazepine, 72% of the administered radioactivity was found in the urine and 28% in the feces. This urinary radioactivity was composed largely of hydroxylated and conjugated metabolites, with only 3% of unchanged Tegretol. Transplacental passage of Tegretol is rapid (30 to 60 minutes), and the drug is accumulated in fetal tissues, with higher levels found in liver and kidney than in brain and lungs.

INDICATIONS AND USAGE

Epilepsy: Tegretol is indicated for use as an anticonvulsant drug. Evidence supporting efficacy of Tegretol as an anticonvulsant was derived from active drug-controlled studies that enrolled patients with the following seizure types:

1. Partial seizures with complex symptomatology (psychomotor, temporal lobe). Patients with these seizures appear to show greater improvement than those with other types.
2. Generalized tonic-clonic seizures (grand mal).
3. Mixed seizure patterns which include the above, or other partial or generalized seizures.

Absence seizures (petit mal) do not appear to be controlled by Tegretol (see PRECAUTIONS, General).

Trigeminal Neuralgia: Tegretol is indicated in the treatment of the pain associated with true trigeminal neuralgia.

Beneficial results have also been reported in glossopharyngeal neuralgia.

This drug is not a simple analgesic and should not be used for the relief of trivial aches or pains.

CONTRAINDICATIONS

Tegretol should not be used in patients with a history of previous bone marrow depression, hypersensitivity to the drug, or known sensitivity to any of the tricyclic compounds, such as amitriptyline, desipramine, imipramine, protriptyline, nortriptyline, etc. Likewise, on theoretical grounds its use with monoamine oxidase inhibitors is not recommended. Before administration of Tegretol, MAO inhibitors should be discontinued for a minimum of fourteen days, or longer if the clinical situation permits.

WARNINGS

Patients with a history of adverse hematologic reaction to any drug may be particularly at risk.

Severe dermatologic reactions including toxic epidermal necrolysis (Lyell's syndrome) and Stevens-Johnson syndrome, have been reported with Tegretol. These reactions have been extremely rare. However, a few fatalities have been reported.

Tegretol has shown mild anticholinergic activity; therefore, patients with increased intraocular pressure should be closely observed during therapy.

Because of the relationship of the drug to other tricyclic compounds, the possibility of activation of a latent psychosis and, in elderly patients, of confusion or agitation should be borne in mind.

PRECAUTIONS

General: Before initiating therapy, a detailed history and physical examination should be made.

Tegretol should be used with caution in patients with a mixed seizure disorder that includes atypical absence seizures, since in these patients Tegretol has been associated with increased frequency of generalized convulsions (see INDICATIONS AND USAGE).

Therapy should be prescribed only after critical benefit-to-risk appraisal in patients with a history of cardiac, hepatic or renal damage, adverse hematologic reaction to other drugs, or interrupted courses of therapy with Tegretol.

Information for Patients: Patients should be made aware of the early toxic signs and symptoms of a potential hematologic problem, such as fever, sore throat, ulcers in the mouth, easy bruising, petechial or purpuric hemorrhage, and should be advised to report to the physician immediately if any such signs or symptoms appear.

Since dizziness and drowsiness may occur, patients should be cautioned about the hazards of operating machinery or automobiles or engaging in other potentially dangerous tasks.

Laboratory Tests: Complete pretreatment blood counts, including platelets and possibly reticulocytes and serum iron, should be obtained as a baseline. If a patient in the course of treatment exhibits low or decreased white blood cell or platelet counts, the patient should be monitored closely. Discontinuation of the drug should be considered if any evidence of significant bone marrow depression develops.

Baseline and periodic evaluations of liver function, particularly in patients with a history of liver disease, must be performed during treatment with this drug since liver damage may occur. The drug should be discontinued immediately in cases of aggravated liver dysfunction or active liver disease.

Baseline and periodic eye examinations, including slit-lamp, funduscopy and tonometry, are recommended since many phenothiazines and related drugs have been shown to cause eye changes.

Baseline and periodic complete urinalysis and BUN determinations are recommended for patients treated with this agent because of observed renal dysfunction.

Monitoring of blood levels (see CLINICAL PHARMACOLOGY) has increased the efficacy and safety of anticonvulsants. This monitoring may be particularly useful in cases of dramatic increase in seizure frequency and for verification of compliance. In addition, measurement of drug serum levels may aid in determining the cause of toxicity when more than one medication is being used.

Thyroid function tests have been reported to show decreased values with Tegretol administered alone.

Hyponatremia has been reported in association with Tegretol use, either alone or in combination with other drugs.

Drug Interactions: The simultaneous administration of phenobarbital, phenytoin, or primidone, or a combination of two, produces a marked lowering of serum levels of Tegretol. The effect of valproic acid on Tegretol blood levels is not clearly established, although an increase in the ratio of active 10, 11-epoxide metabolite to parent compound is a consistent finding.

The half-lives of phenytoin, warfarin, doxycycline, and theophylline were significantly shortened when administered concurrently with Tegretol. Haloperidol and valproic acid serum levels may be reduced when these drugs are administered with Tegretol. The doses of these drugs may therefore have to be increased when Tegretol is added to the therapeutic regimen.

Concomitant administration of Tegretol with erythromycin, cimetidine, propoxyphene, isoniazid, fluoxetine or calcium channel blockers has been reported to result in elevated plasma levels of carbamazepine resulting in toxicity in some cases. Also, concomitant administration of carbamazepine and lithium may increase the risk of neurotoxic side effects.

Alterations of thyroid function have been reported in combination therapy with other anticonvulsant medications.

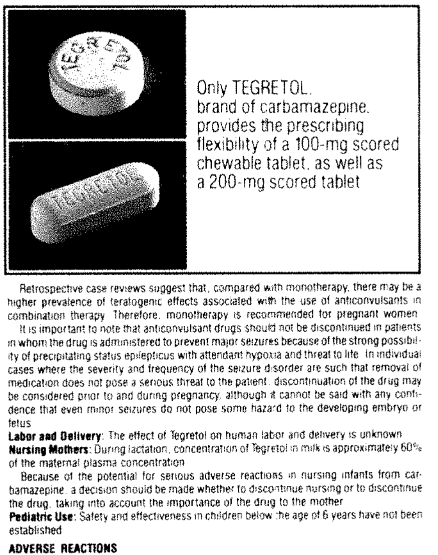
Breakthrough bleeding has been reported among patients receiving concomitant oral contraceptives and their reliability may be adversely affected.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Carbamazepine, when administered to Sprague-Dawley rats for two years in the diet at doses of 25, 75, and 250 mg/kg/day, resulted in a dose-related increase in the incidence of hepatocellular tumors in females and of benign interstitial cell adenomas in the testes of males.

Carbamazepine must, therefore, be considered to be carcinogenic in Sprague-Dawley rats. Bacterial and mammalian mutagenicity studies using carbamazepine produced negative results. The significance of these findings relative to the use of carbamazepine in humans is, at present, unknown.

Pregnancy Category C: Tegretol has been shown to have adverse effects in reproduction studies in rats when given orally in dosages 10-25 times the maximum human daily dosage of 1200 mg. In rat teratology studies, 2 of 135 offspring showed kinked ribs at 250 mg/kg and 4 of 119 offspring at 650 mg/kg showed other anomalies (cleft palate, 1; talipes, 1; anophthalmos, 2). In reproduction studies in rats, nursing offspring demonstrated a lack of weight gain and an unkempt appearance at a maternal dosage level of 200 mg/kg.

There are no adequate and well-controlled studies in pregnant women. Epidemiological data suggest that there may be an association between the use of carbamazepine during pregnancy and congenital malformations, including spina bifida. Tegretol should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.



Only TEGRETOL,
brand of carbamazepine,
provides the prescribing
flexibility of a 100-mg scored
chewable tablet, as well as
a 200-mg scored tablet

Retrospective case reviews suggest that, compared with monotherapy, there may be a higher prevalence of teratogenic effects associated with the use of anticonvulsants in combination therapy. Therefore, monotherapy is recommended for pregnant women.

It is important to note that anticonvulsant drugs should not be discontinued in patients in whom the drug is administered to prevent major seizures because of the strong possibility of precipitating status epilepticus with attendant hypoxia and threat to life. In individual cases where the severity and frequency of the seizure disorder are such that removal of medication does not pose a serious threat to the patient, discontinuation of the drug may be considered prior to and during pregnancy, although it cannot be said with any confidence that even minor seizures do not pose some hazard to the developing embryo or fetus.

Labor and Delivery: The effect of Tegretol on human labor and delivery is unknown.

Nursing Mothers: During lactation, concentration of Tegretol in milk is approximately 60% of the maternal plasma concentration.

Because of the potential for serious adverse reactions in nursing infants from carbamazepine, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use: Safety and effectiveness in children below the age of 6 years have not been established.

ADVERSE REACTIONS

If adverse reactions are of such severity that the drug must be discontinued, the physician must be aware that abrupt discontinuation of any anticonvulsant drug in a responsive epileptic patient may lead to seizures or even status epilepticus with its life-threatening hazards.

The most severe adverse reactions have been observed in the hemopoietic system (see boxed WARNING), the skin and the cardiovascular system.

The most frequently observed adverse reactions, particularly during the initial phases of therapy, are dizziness, drowsiness, unsteadiness, nausea, and vomiting. To minimize the possibility of such reactions, therapy should be initiated at the low dosage recommended.

The following additional adverse reactions have been reported:

Hemopoietic System. Aplastic anemia, agranulocytosis, pancytopenia, bone marrow depression, thrombocytopenia, leukopenia, leukocytosis, eosinophilia, acute intermittent porphyria.

Skin: Pruritic and erythematous rashes, urticaria, toxic epidermal necrolysis (Lyell's syndrome) (see WARNINGS), Stevens-Johnson syndrome (see WARNINGS), photosensitivity reactions, alterations in skin pigmentation, exfoliative dermatitis, erythema multiforme and nodosum, purpura, aggravation of disseminated lupus erythematosus, alopecia, and diaphoresis. In certain cases, discontinuation of therapy may be necessary. Isolated cases of hirsutism have been reported, but a causal relationship is not clear.

Cardiovascular System. Congestive heart failure, edema, aggravation of hypertension, hypotension, syncope and collapse, aggravation of coronary artery disease, arrhythmias and AV block, primary thrombophlebitis, recurrence of thrombophlebitis, and adenopathy or lymphadenopathy.

Some of these cardiovascular complications have resulted in fatalities. Myocardial infarction has been associated with other tricyclic compounds.

Liver: Abnormalities in liver function tests, cholestatic and hepatocellular jaundice, hepatitis.

Respiratory System. Pulmonary hypersensitivity characterized by fever, dyspnea, pneumonitis or pneumonia.

Genitourinary System. Urinary frequency, acute urinary retention, oliguria with elevated blood pressure, azotemia, renal failure, and impotence. Albuminuria, glycosuria, elevated BUN and microscopic deposits in the urine have also been reported.

Testicular atrophy occurred in rats receiving Tegretol orally from 4 to 52 weeks at dosage levels of 50 to 400 mg/kg/day. Additionally, rats receiving Tegretol in the diet for two years at dosage levels of 25, 75, and 250 mg/kg/day had a dose-related incidence of testicular atrophy and aspermatogenesis. In dogs, it produced a brownish discoloration, presumably a metabolite, in the urinary bladder at dosage levels of 50 mg/kg and higher. Relevance of these findings to humans is unknown.

Nervous System. Dizziness, drowsiness, disturbances of coordination, confusion, headache, fatigue, blurred vision, visual hallucinations, transient diplopia, oculomotor disturbances, nystagmus, speech disturbances, abnormal involuntary movements, peripheral neuritis and paresthesias, depression with agitation, talkativeness, tinnitus, and hyperacusis.

There have been reports of associated paralysis and other symptoms of cerebral arterial insufficiency, but the exact relationship of these reactions to the drug has not been established.

Digestive System: Nausea, vomiting, gastric distress and abdominal pain, diarrhea, constipation, anorexia, and dryness of the mouth and pharynx, including glossitis and stomatitis.

Eyes. Scattered, punctate, cortical lens opacities, as well as conjunctivitis, have been reported. Although a direct causal relationship has not been established, many phenothiazines and related drugs have been shown to cause eye changes.

Musculoskeletal System. Aching joints and muscles, and leg cramps.

Metabolism. Fever and chills. Inappropriate antidiuretic hormone (ADH) secretion syndrome has been reported. Cases of frank water intoxication, with decreased serum sodium (hyponatremia) and confusion, have been reported in association with Tegretol use (see PRECAUTIONS, Laboratory Tests).

Other. Isolated cases of a lupus erythematosus-like syndrome have been reported. There have been occasional reports of elevated levels of cholesterol, HDL cholesterol and triglycerides in patients taking anticonvulsants.

A case of aseptic meningitis, accompanied by myoclonus and peripheral eosinophilia, has been reported in a patient taking carbamazepine in combination with other medications. The patient was successfully dechallenged, and the meningitis reappeared upon rechallenge with carbamazepine.

DRUG ABUSE AND DEPENDENCE

No evidence of abuse potential has been associated with Tegretol, nor is there evidence of psychological or physical dependence in humans.

OVERDOSAGE

Acute Toxicity

Lowest known lethal dose: adults, >60 g (39-year-old man). Highest known doses survived: adults, 30 g (31-year-old woman); children, 10 g (6-year-old boy); small children, 5 g (3-year-old girl).

Oral LD 50 in animals (mg/kg): mice, 1100-3750; rats, 3850-4025; rabbits, 1500-2680; guinea pigs, 920.

Signs and Symptoms

The first signs and symptoms appear after 1-3 hours. Neuromuscular disturbances are the most prominent. Cardiovascular disorders are generally milder, and severe cardiac complications occur only when very high doses (>60 g) have been ingested.

Respiration. Irregular breathing, respiratory depression.

Cardiovascular System. Tachycardia, hypotension or hypertension, shock, conduction disorders.

Nervous System and Muscles. Impairment of consciousness ranging in severity to deep coma. Convulsions, especially in small children. Motor restlessness, muscular twitching, tremor, athetoid movements, opisthotonos, ataxia, drowsiness, dizziness, mydriasis, nystagmus, adiadochokinesia, ballism, psychomotor disturbances, dysmetria. Initial hyperreflexia, followed by hyporeflexia.

Gastrointestinal Tract. Nausea, vomiting.

Kidneys and Bladder. Anuria or oliguria, urinary retention.

Laboratory Findings. Isolated instances of overdosage have included leukocytosis, reduced leukocyte count, glycosuria and acetonuria. EEG may show dysrhythmias.

Combined Poisoning: When alcohol, tricyclic antidepressants, barbiturates or hydantoins are taken at the same time, the signs and symptoms of acute poisoning with Tegretol may be aggravated or modified.

Treatment

The prognosis in cases of severe poisoning is critically dependent upon prompt elimination of the drug, which may be achieved by inducing vomiting, irrigating the stomach, and by taking appropriate steps to diminish absorption. If these measures cannot be implemented without risk on the spot, the patient should be transferred at once to a hospital, while ensuring that vital functions are safeguarded. There is no specific antidote.

Elimination of the Drug. Induction of vomiting.

Gastric lavage. Even when more than 4 hours have elapsed following ingestion of the drug, the stomach should be repeatedly irrigated, especially if the patient has also consumed alcohol.

Measures to Reduce Absorption. Activated charcoal, laxatives.

Measures to Accelerate Elimination. Forced diuresis.

Dialysis is indicated only in severe poisoning associated with renal failure. Replacement transfusion is indicated in severe poisoning in small children.

Respiratory Depression. Keep the airways free; resort, if necessary, to endotracheal intubation, artificial respiration, and administration of oxygen.

Hypotension, Shock: Keep the patient's legs raised and administer a plasma expander. If blood pressure fails to rise despite measures taken to increase plasma volume, use of vasoactive substances should be considered.

Convulsions. Diazepam or barbiturates.

Warning. Diazepam or barbiturates may aggravate respiratory depression (especially in children), hypotension, and coma. However, barbiturates should not be used if drugs that inhibit monoamine oxidase have also been taken by the patient either in overdosage or in recent therapy (within one week).

Surveillance. Respiration, cardiac function (ECG monitoring), blood pressure, body temperature, pupillary reflexes, and kidney and bladder function should be monitored for several days.

Treatment of Blood Count Abnormalities. If evidence of significant bone marrow depression develops, the following recommendations are suggested: (1) stop the drug, (2) perform daily CBC, platelet and reticulocyte counts, (3) do a bone marrow aspiration and trephine biopsy immediately and repeat with sufficient frequency to monitor recovery.

Special periodic studies might be helpful as follows: (1) white cell and platelet antibodies, (2) 59Fe—ferrokinetic studies, (3) peripheral blood cell typing, (4) cytogenetic studies on marrow and peripheral blood, (5) bone marrow culture studies for colony-forming units, (6) hemoglobin electrophoresis for A_2 and F hemoglobin, and (7) serum folic acid and B_{12} levels.

A fully developed aplastic anemia will require appropriate, intensive monitoring and therapy, for which specialized consultation should be sought.

DOSAGE AND ADMINISTRATION

Monitoring of blood levels has increased the efficacy and safety of anticonvulsants (see PRECAUTIONS, Laboratory Tests). Dosage should be adjusted to the needs of the individual patient. A low initial daily dosage with a gradual increase is advised. As soon as adequate control is achieved, the dosage may be reduced very gradually to the minimum effective level. Tablets should be taken with meals.

Epilepsy (see INDICATIONS AND USAGE)

Adults and children over 12 years of age—Initial: 200 mg b.i.d. Increase at weekly intervals by adding up to 200 mg per day using a t.i.d. or q.i.d. regimen until the best response is obtained. Dosage should generally not exceed 1000 mg daily in children 12 to 15 years of age, and 1200 mg daily in patients above 15 years of age. Doses up to 1600 mg daily have been used in adults in rare instances. ***Maintenance:*** Adjust dosage to the minimum effective level, usually 800-1200 mg daily.

Children 6-12 years of age—Initial: 100 mg b.i.d. Increase at weekly intervals by adding 100 mg per day using a t.i.d. or q.i.d. regimen until the best response is obtained. Dosage should generally not exceed 1000 mg. ***Maintenance:*** Adjust dosage to the minimum effective level, usually 400-800 mg daily.

Combination Therapy: Tegretol may be used alone or with other anticonvulsants. When added to existing anticonvulsant therapy, the drug should be added gradually while the other anticonvulsants are maintained or gradually decreased, except phenytoin, which may have to be increased (see PRECAUTIONS, Drug Interactions and Pregnancy Category C).

Trigeminal Neuralgia (see INDICATIONS AND USAGE)

Initial: 100 mg b.i.d. on the first day for a total daily dose of 200 mg. This daily dose may be increased by up to 200 mg a day using increments of 100 mg every 12 hours only as needed to achieve freedom from pain. Do not exceed 1200 mg daily.

Maintenance: Control of pain can be maintained in most patients with 400 mg to 800 mg daily. However, some patients may be maintained on as little as 200 mg daily, while others may require as much as 1200 mg daily. At least once every 3 months throughout the treatment period, attempts should be made to reduce the dose to the minimum effective level or even to discontinue the drug.

HOW SUPPLIED

Chewable Tablets 100 mg—round, red-speckled, pink, single-scored (imprinted Tegretol on one side and 52 twice on the scored side)

Bottles of 100	NDC 58887-052-30
Unit Dose (blister pack)	
Box of 100	
(strips of 10)	NDC 58887-052-32

Tablets 200 mg—capsule-shaped, pink, single-scored (imprinted Tegretol on one side and 27 twice on the scored side)

Bottles of 100	NDC 58887-027-30
Bottles of 1000	NDC 58887-027-40
Unit Dose (blister pack)	
Box of 100	
(strips of 10)	NDC 58887-027-32

Samples, when available, are identified by the word *SAMPLE* appearing on each tablet.

Protect from moisture.

Dispense in tight container (USP).

Also available as: Tegretol suspension 100 mg/5 ml, in 450 ml bottles.

Printed in U.S.A. C91-18 (Rev. 9/91)

Ultrasound Findings in Spontaneous Carotid Artery Dissection

The Value of Duplex Sonography

Matthias Sturzenegger, MD

• Extracranial and transcranial Doppler and duplex sonographic findings in six patients with internal carotid artery dissection proven by angiography is reported. Extracranial Doppler analysis showed occlusion without a recordable signal from the internal carotid artery at any level or stenosis with accelerated flow in the high cervical segment. Transcranial Doppler findings demonstrated the hemodynamic consequences of the internal carotid artery occlusion or stenosis with collateral flow across the circle of Willis and also showed the dampened pulse wave of the middle cerebral artery ipsilateral to the dissection. In duplex sonography, the indirect signs indicating internal carotid artery dissection were a patent carotid bifurcation and proximal internal carotid artery segment but with no or only a short systolic flow signal. Atherosclerotic wall changes were absent, an important finding that suggests nonatherosclerotic stenosis or occlusion. Direct signs making the diagnosis likely were a tapering of the internal carotid artery lumen distal to the bulb, an irregular membrane crossing the vessel lumen, and the demonstration of a true lumen with flow and a false one without flow. While cerebral angiography is still considered the gold standard, ultrasound may become the primary modality for early diagnosis. Doppler and duplex examinations help to indicate angiography and are the methods of choice for follow-up investigations. They clearly demonstrate spontaneous recanalization with normalization of carotid circulation or, in case of persistent occlusion, improvement of collateral blood supply. Sequential examinations may prove helpful to determine the duration of anticoagulant treatment.

(*Arch Neurol.* 1991;48:1057-1063)

The cervical part of the internal carotid artery (ICA) is by far the most frequent site of spontaneous wall dissection,[1-3] but any brain-supplying artery may be affected.[4] The exact frequency is unknown, but it may be quite underestimated. With less rigid indications for cerebral angiography[5-7] in the last few years, an increasing number of patients with spontaneous dissection of the ICA (ICD) have been identified.[8] From this experience, we have learned that the clinical presentation of ICD may be extremely variable, ranging from the patient with unspecific headache or even no clinical symptoms and signs to the patient with severe stroke and rapidly ensuing death. These clinical extremes usually do not give rise to further investigations, and the real cause, ICD, goes unrecognized.

Younger patients are preferentially affected: Hart and Miller[9] found two cases (2%) among 100 patients with stroke under the age of 40 years, and Bogousslavsky and Regli[10] found nine cases (22%) among 41 patients with stroke under the age of 30 years. Mean age at presentation in a group of 146 cases[2] was 45 years; 70% were between 35 and 50 years old. The younger age at presentation is suggestive of ICD rather than atherosclerotic carotid disease.[2,4] Considering all patients with stroke, ICD is a rare cause of stroke: among a series of 1200 consecutive patients with stroke,[11] 30 (2.5%) had ICD. In another series of 4531 patients examined with cerebral angiography because of acute cerebrovascular symptoms,[12] extracranial carotid artery dissection was diagnosed in 11 (0.24%).

When the characteristic triad of facial or neck pain, ipsilateral oculosympathetic paresis, and hemispheric ischemic symptoms is present, diagnosis may be strongly suspected on clinical grounds.[2,4,13-16] For definite diagnosis, angiography is required, which can show characteristic but also variable signs.[3,4,17-21] The findings, except double lumen, are nonspecific. Differential diagnosis includes arterial compression or invasion by tumor or pharyngeal inflammation, congenital hypoplasia, vasculitis, radiation-induced arteriopathy, and vasospasm.

In general, prognosis is good, and spontaneous recanalization occurs in more than 80% of patients.[2,4] However, persisting disability can result,[21,22] owing to ensuing stroke. Considering patients with ICD and stroke,[11] prognosis is clearly worse: recanalization occurs in only 60% and death in 23%, and 48% of the patients remain severely disabled. Stroke is, as known from angiography,[18,23] mostly due to embolism from local thrombosis at the site of dissection. Rarely, insufficient collateral blood supply causes hemodynamic infarction.

Because of the danger of embolism, early anticoagulation is considered the treatment of choice. However, its effectiveness has not been proved yet by a randomized controlled study. On the other hand, to my knowledge there is no case of ICD reported in the literature in which symptoms worsened with antico-

Table 1.—Clinical Findings*

Patient No./ Age, y/Sex	Symptoms	Signs	Vascular Risk Factors	Treatment	Evolution
1/49/M	Recurrent TIA (L hemiparesis), pain R eye and temple	None	Migraine, hypertension, smoking, cholesterol	Heparin sodium, coumarin	Resolution after 12 d
2/42/F	R hemiparesis, aphasia, occipital headache	R hemiparesis	Migraine, hypertension	Heparin, coumarin	Partial recanalization with persisting slight stenosis after 15 wk
3/41/M	Recurrent R amaurosis fugax, recurrent TIA (R hemiparesis), pain R temple and cheek	Loss of consciousness, R hemiparesis, transient aphasia, bruit R carotid	None	Aspirin	Resolution on both sides after 2 mo
4/41/M	R hemiparesis, aphasia, frontal headache	R hemiparesis	None	Heparin, coumarin	Persisting occlusion after 2 mo, better intracranial collateral flow
5/40/M	Recurrent TIA (L hemiparesis), gait disturbance, pain R eye and temple	Partial HS on R, hemianopia to L, L hemiparesis, L sensory neglect, CT: infarction	Migraine, hypertension	Heparin, coumarin	Symmetric BFV in both MCAs after 5 d, complete recanalization after 6 wk
6/41/M	Recurrent TIA (asphasia), pain L eye and forehead	Partial HS, none on L	None	Heparin, coumarin	Resolution after 10 wk

*TIA indicates transient ischemic attack; HS, Horner's syndrome; CT, computed tomography; BFV, blood flow velocity; and MCA, middle cerebral artery.

agulant therapy. If anticoagulation is beneficial, early diagnosis is essential for the treatment of patients with ICD, a goal that can be achieved with combined ultrasonographic examination (CUE) using conventional extracranial direct and indirect Doppler sonography, transcranial Doppler sonography (TCD), and duplex scanning. I report my experience using CUE in six patients with ICD in the extracranial segment verified by angiography.

PATIENTS AND METHODS

Duplex Examination

A high-resolution, real-time, duplex ultrasound system (Diasonics SPA 1000, Sonotron Holding AG, Zug, Switzerland) was used that consisted of a 10-MHz echotomography imaging probe and a 4.5-MHz pulsed-wave Doppler probe with real-time gray-scale Fast-Fourier transform Doppler spectrum analysis. Common carotid artery (CCA), bulb, ICA, external carotid artery (ECA), and vertebral arteries were imaged on both sides.

Extracranial Doppler Examination

The technique for extracranial direct and indirect Doppler sonographic examination has been described in detail previously.[24] I used the same device as for TCD recordings, which is described below. The CCA, ECA, ICA, subclavian artery, and vertebral artery at the atlas were examined by continuous insonnation on both sides. Supratrochlear and ophthalmic arteries (OpAs), as well as carotid siphons, were measured by a transorbital approach.

TCD Examination

The technique for TCD recordings has been described in detail previously.[25-28] A microprocessor-controlled directional pulsed Doppler device operating at 2 MHz was used for all TCD ultrasound examinations (TC2-64, Eden Medizinische Elektronic GmbH, Ueberlingen, Germany). The middle cerebral artery (MCA), anterior cerebral artery, posterior cerebral artery, and ICA bifurcation were analyzed at different depths by a transtemporal approach and the intracranial vertebral and basilar arteries were analyzed through the occipital foramen. Systolic, diastolic, and mean blood flow velocity (BFV) were measured in each vessel. Pulsatility index (PI) was calculated according to the following formula: PI = (systolic BFV − diastolic BFV)/mean BFV.[25] The values of 52 normal controls served as reference. The MCA-BFV and PI values of the six patients were compared with those of the controls.

Cerebral Angiography

Selective CCA angiograms were obtained in all patients. Catheterizations were performed by the percutaneous femoral approach. In one case (case 3), direct CCA puncture was performed. Six French polyethylene catheters and a nonionic, low-osmolar contrast agent were used.

Statistical analysis was performed using simple regression analysis and the unpaired and paired t test.

RESULTS

Six patients (five men and one woman with a mean age of 42.5 years [range, 40 to 49 years]) admitted within a year with angiographically proved ICD were analyzed. Five had unilateral dissection and one (case 3) had bilateral dissection. The clinical findings are summarized in Table 1. Lower cranial nerve palsy did not occur. A computed tomographic scan was normal in five patients and showed MCA infarction in one (case 5). There was no preceding trauma.

Extracranial Doppler sonography showed ICA occlusion on one side in all patients and additional stenosis on the other side in case 3. Four patients had collateral blood supply from the ipsilateral ECA to ICA territory and patient 3 had collateral supply across both OpAs with retrograde flow.

Transcranial Doppler sonography showed reduced MCA-BFV and PI on the side of dissection in five patients compared with the contralateral side ($P = .001$ for BFV, $P = .002$ for PI) as well as compared with the controls ($P = .0001$ for BFV, $P = .0001$ for PI). An additional patient had symmetric MCA velocities but reduced PI on the side of the lesion (case 2). All had collateral blood supply across the anterior communicating artery from the contralateral ICA. Mean BFV and PI with the side differences of patients and controls are given in Table 2. In controls, there was a correlation between right and left MCA-BFV ($r = .955$, $F = 516.2$, $P = .0001$) and PI ($r = .768$, $F = 71.8$, $P = .0001$) and there was no side difference ($P = .83$ for both). In patients, there was no correlation between MCA-BFV ($r = .692$, $F = 3.7$, $P = .13$) and PI ($r = .242$, $F = 0.25$, $P = .64$) ipsilateral and contralateral to the dissection side, and the side differences were obvious ($P = .001$ for BFV and $P = .002$ for PI).

Duplex Examination

No patient had atherosclerotic wall changes. All the proximal ICA segments were patent on the "occluded" side, two with a residual "stump flow" and four without recordable flow signal. There was a "membrane" visible crossing the ICA lumen in four arteries, producing the picture of double lumen not compressible by the probe (Fig 1).

Table 2.—Transcranial Doppler Findings*

	L or Ipsilateral MCA		R or Contralateral MCA		Mean Difference	
Group	BFV	PI	BFV	PI	BFV	PI
Controls						
Mean ± SD	64.5 ± 10.5	0.76 ± 0.15	64.1 ± 11.6	0.75 ± 0.15	0.46 ± 3.6	0.01 ± 0.1
Range	45-90	0.48-1.24	41-90	0.51-1.37	17	0.55
Patients						
Mean ± SD	43.2 ± 9.5	0.46 ± 0.08	61.2 ± 11.4	0.65 ± 0.08	18 ± 8.4	0.2 ± 0.1
Range	33-55	0.33-0.57	48-82	0.52-0.75	24	0.26

*MCA indicates middle cerebral artery; BFV, blood flow velocity; and PI, pulsatility index. Left and right MCAs were examined in controls, ipsilateral and contralateral MCAs in patients. In cases with bilateral dissection, the ipsilateral side indicates the side more occluded.

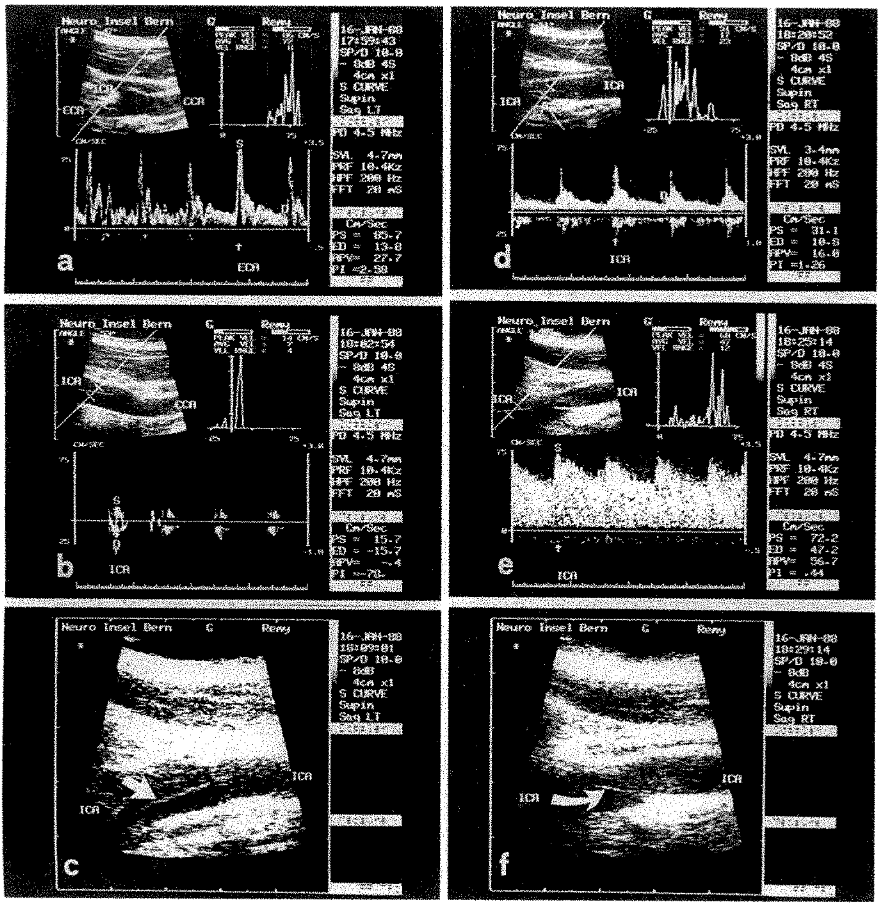

Fig 1.—Results of initial Duplex scanning (case 3): a, open left carotid bifurcation and identification of external carotid artery (ECA); b, only short systolic flow signal in the most proximal left internal carotid artery (ICA; stump flow); c, membrane (arrow) crossing lumen of left ICA in a more distal segment; d, preserved flow signal in proximal right ICA; e, high blood flow velocity indicating stenosis in more distal segment of right ICA, membrane crossing vessel lumen; and f, membrane crossing vessel lumen of right ICA (arrow). CCA indicates common carotid artery.

Angiography

Five patients (cases 1, 2, 3, 5, and 6) had bilateral, and one (case 4) had unilateral, carotid angiography. One patient (case 3) had bilateral dissection; consequently, seven dissected ICAs could be analyzed.

In all of them, the carotid bifurcation and at least the most proximal 2 cm of the ICA were normal. Four showed smoothly tapering stenoses (cases 3 [left], 4, 5, and 6) starting 3 to 4 cm distal to the bifurcation, in all extending up to the base of the skull (in case 5 probably to the siphon segment). In three, the stenoses were high grade with a filiform residual lumen resulting in a "string sign" (cases 4, 5 and 6). Abrupt return to normal caliber was noted in all at the entrance of the carotid canal. Two showed irregular segmental stenosis (cases 1 and 3 [right]), in both cases of the prepetrosal segment and with abrupt reconstitution of a normal lumen width at the entrance of the carotid canal. In case 1, stenosis started immediately distal to a carotid kinking.

There was a tapering occlusion starting 2 cm distal to the bifurcation with a flame-shaped stump in one artery (case 2). Collateral blood supply across the anterior part of the circle of Willis (anterior communicating artery) was confirmed in all five cases with bilateral carotid angiograms.

No patient showed pseudoaneurysm formation or signs indicative of fibromuscular dysplasia. None had atherosclerotic wall lesions (Fig 2). The results of ultrasound findings and angiography are summarized in Table 3.

REPORT OF A CASE

A 41-year-old technician had no vascular risk factors. Three weeks before his hospitalization, he felt increasing pain in his right temple and cheek. Plain roentgenograms showed an opacified maxillary sinus, and polyposis was considered as the likely cause of his pain. The patient was admitted for sinuscopy. Soon after premedication with intramuscular atropine sulfate (0.5 mg) and morphine chloride (5 mg), he fainted. When he regained consciousness after several minutes, there was right-sided hemiplegia and asphasia clearing within 2 hours. Physical examination revealed a bruit over the right carotid artery. Results of routine blood laboratory tests, electrocardiogram, and computed tomography were normal. Now, on detailed questioning, he reported several attacks of blurred vision or transient blindness of his right eye, lasting 1 or 2 minutes, in the days before admission. In addition, he had had three episodes of feeling cold and heaviness or loss of motor control of his right arm and hand.

Doppler analysis (Fig 3) showed reduced diastolic flow and increased PI in the left CCA. The left ICA could not be identified. The left ECA showed high diastolic flow resembling an intracranial vessel. The BFVs in the right CCA, the ECA, and the proximal part of the ICA were normal. However, in the high cervical segment of the right ICA, there was increased BFV over a long segment up to the base of the skull. Both OpAs showed reversed flow direction toward the intracranial region.

The TCD analysis (Fig 3) revealed reduced BFV and reduced PI in the left MCA. The left anterior cerebral artery showed reversal of flow direction. High BFVs in the left posterior cerebral artery indicated collateral flow from the posterior circulation.

Duplex scanning (Fig 1) showed a widely patent left proximal ICA, but only minimal systolic intraluminal flow signal (stump flow). In its more distal part, a membranelike structure traversing the vessel lumen could be visualized. The right proximal ICA was also patent, and flow was normal. Still more distally, there was a membranelike structure in the vessel lumen, and at this site high BFVs were present, indicating stenosis.

A diagnosis of left ICA occlusion and right ICA stenosis distal to their origin from the bulb was made, with collateral flow to the left carotid territory across the anterior and posterior communicating arteries. The patent proximal ICA segments and the membranes traversing the vessel lumen suggested bilateral ICDs. Cerebral four-vessel angiography (Fig 2) showed a normal proximal ICA on both sides. In the higher cervical part, the left one showed progressive narrowing to a stringlike lumen with abrupt luminal reconstitution at the entry to the petrosal canal. There was moderate stenosis of the right ICA in the higher cervical part, again with abrupt reconstitution of the vessel lumen at the base of the skull. Intracranially, flow was from the right ICA to the left across the anterior communicating artery. Because of the smooth boundaries of luminal narrowings, bilateral carotid hypoplasia was diagnosed by the radiologist (which did not explain the sudden neurologic symptoms).

Doppler control 10 days later showed normalized BFV in both CCAs. Both ICAs could be identified with normal BFV in their proximal parts but with high BFV in their upper cervical segments due to stenosis. The MCA-BFV was symmetric. The anterior cerebral artery and OpA flows were antegrade on both sides. Duplex scanning showed flow in both ICAs, but there were still stenoses due to membranelike structures. This flow reconstitution clearly made hypoplasia unlikely and a diagnosis of dissection more favorable. Doppler reexamination 2 months later showed normal results proving spontaneous recanalization and yielded the diagnosis of spontaneous bilateral ICD. The patient has remained asymptomatic taking aspirin.

COMMENT

Because the clinical presentation of ICD may be extremely variable,[2] the diagnosis cannot be made on clinical grounds alone. Carotid angiography is at present still the method of choice for definite diagnosis. Though it has become much less risky owing to technical achievements,[5-7] it remains an invasive procedure that should not be performed when there is only weak clinical suspicion of ICD. In these situations, an easily available, noninvasive method is desirable that can confirm the suspicion and allow the selective use of carotid angiography.

Conventional direct and indirect (pulsed- or continuous-wave) Doppler sonography of the extracranial carotid arteries and their branches[24] can reveal

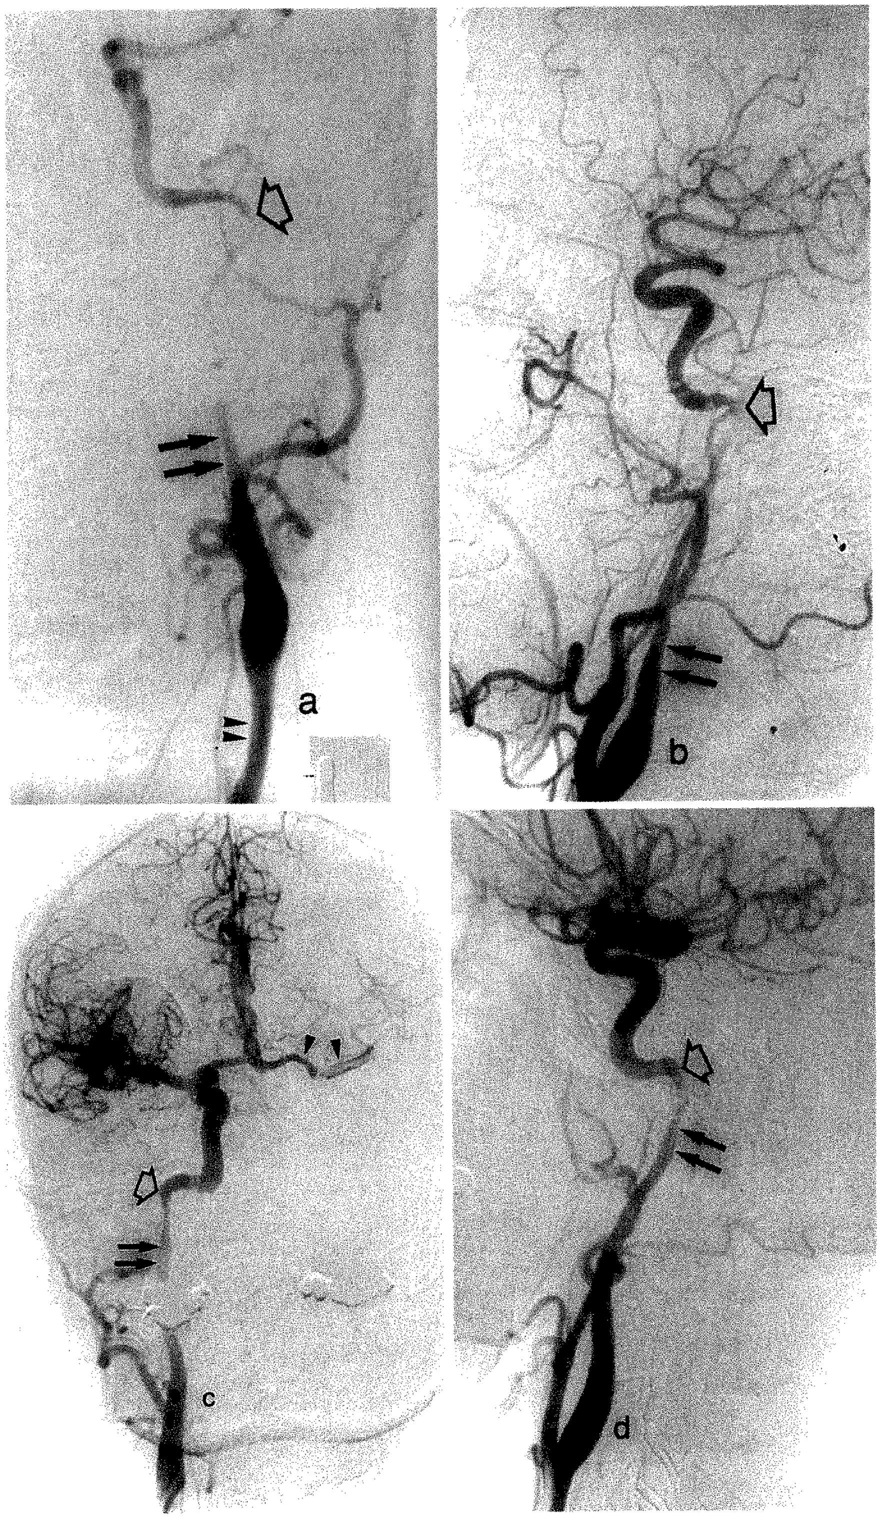

Fig 2.—Left common carotid arteriogram in case 3 (a, anteroposterior projection; b, lateral view) demonstrates common carotid narrowing (arrowheads in a) resulting from subintimal injection following direct artery puncture. Carotid bifurcation and proximal 3 cm of internal carotid artery (ICA) are normal. Then, smoothly tapering stenosis of left cervical ICA (arrows in a and b) with severe slowing of flow is noted, extending up to the skull base, where abrupt return to normal caliber is seen at entrance of carotid canal (open arrows in a and b). There is no filling of left anterior cerebral artery. Right common carotid arteriogram (c, anteroposterior projection; d, lateral view) again shows normal carotid bifurcation and proximal right ICA. Irregular segmental moderate stenosis of the high cervical prepetrosal ICA segment (arrows in c and d) is demonstrated with abrupt reconstitution of normal lumen width at the entrance of the carotid canal (open arrows in c and d). There is collateral flow from right to left carotid territory across anterior circle of Willis (arrowheads in c).

Table 3.—Summary of Results*

Patient No./ Age, y/Sex	Arteriography	ECD	TCD	Duplex Sonography
1/49/M	Segmental stenosis of high cervical R ICA; collateral flow across circle of Willis, L to R	R ICA occlusion, R OpA retrograde	R MCA BFV ↓; collateral flow across AComA, L to R	Patent proximal R ICA with stump flow
2/42/F	Tapering occlusion of L ICA; collateral flow across circle of Willis, R to L	L ICA occlusion, OpA both orthograde	L MCA PI ↓; collateral flow across AComA, R to L	Patent proximal L ICA, no intraluminal flow; membrane with double lumen
3/41/M	L ICA: string sign, reconstitution at skull base; R ICA: high cervical segmental stenosis, reconstitution at skull base; collateral flow across circle of Willis, R to L	L ICA occlusion, R ICA stenosis (high cervical segment), OpAs both retrograde (bilateral dissection)	L MCA BFV ↓; collateral flow across AComA, R to L and from vertebrobasilar system	Patent proximal L ICA without flow; membrane L ICA (distal); membrane R ICA (distal and stenosis); double lumen
4/41/M	L ICA: string sign, reconstitution at skull base	L ICA occlusion, L OpA retrograde	L MCA BFV ↓; collateral flow across AComA, R to L	Patent proximal L ICA with stump flow
5/40/M	R ICA: string sign up to cavernous segment; collateral flow across circle of Willis, L to R	R ICA occlusion, R OpA retrograde	R MCA BFV ↓; collateral flow across AComA, L to R; R MCA, no reactivity on CO_2 breathing	Patent proximal R ICA without flow
6/41/M	L ICA: string sign, reconstitution at skull base; collateral flow across circle of Willis, R to L	L ICA occlusion, L OpA retrograde	L MCA BFV ↓; collateral flow across AComA, R to L	Patent proximal L ICA without flow; membrane with double lumen not compressible

*ECD indicates extracranial Doppler sonography; TCD, transcranial Doppler sonography; ICA, internal carotid artery; OpA, ophthalmic artery; MCA, middle cerebra artery; BFV, blood flow velocity; AComA, anterior communicating artery; and PI, pulsatility index. Occlusion on ECD indicates no signal from ICA at origin from bulb an at skull base.

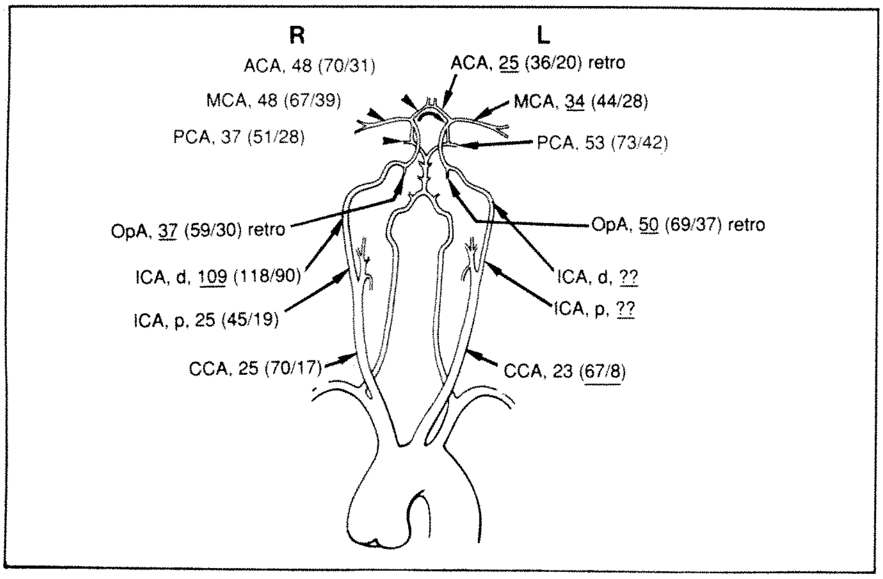

Fig 3.—Results of initial extracranial and transcranial Doppler analysis in case 3 (see text for details). ACA indicates anterior cerebral artery; retro, retrograde; MCA, middle cerebral artery; PCA, posterior cerebral artery; OpA, ophthalmic artery; ICA, internal carotid artery (d and p indicating distal and proximal); and CCA, common carotid artery. The numbers represent the values of blood flow velocities in each vessel: mean (systolic/diastolic). The pathological values are underlined.

occlusion or stenosis if it exceeds 50% of lumen diameter. The technique does not yield further information about origin. Only the finding of a stenosis located in the upper cervical ICA segment or extending over a long distance may suggest dissection,[22,29] but this is not a specific sign. Transcranial Doppler sonography,[25-28] though detecting the effects on intracranial circulation including collateral blood flow, does not help in further differentiating the origin of stenosis or occlusion.

The primary goal of CUE is the differentiation of ICD from occlusion or stenosis due to other causes such as atherosclerosis. Atherosclerotic lesions of the brain-supplying arteries show a predilection for the carotid bifurcation.[3] Spontaneous ICD, on the other hand, is usually localized in the middle or upper cervical segment of the ICA or begins at least 2 to 3 cm distal to the carotid bifurcation.[1,3,16,17,20,23] These anatomic facts and the easy accessibility of the carotid bifurcation in most patients by duplex scanning make this method suitable for differentiation.

When conventional Doppler sonography indicates ICA stenosis or occlusion, the indirect findings at duplex scanning listed in Table 4[31-34] suggest a dissection. These are ultimately nonspecific findings, and the diagnosis may be hampered when there is the simultaneous presence of atheromatous plaques[22] or when the ICD starts already at the bifurcation.[20,21] Therefore, direct visualization of the dissection should be attempted. Direct and more specific signs of ICD at duplex scanning are listed in Table 4.

Internal carotid artery dissection is virtually always extracranial but varies considerably in extent.[21] It typically occurs distal to the extracranial bifurcation,[4] often at or around the C-2 vertebral level.[2,21] Because this region may be beyond the range of carotid imaging by

Table 4.—Duplex Sonography: Findings Suggesting ICA Dissection*

- Indirect findings
  - No atheromatous plaques are visible in carotid bifurcation
  - Bulb and proximal segment of ICA are patent
  - No flow signal or high-resistance flow pattern (short, only
    systolic flow peak [stump flow] or bidirectional [reverberating] systolic flow) in proximal ICA
  - Lack of wall pulsations
- Direct signs
  - Tapering of ICA lumen starting ≥2 cm distal to bulb
  - Irregular "membrane" crossing ICA lumen (Fig 1)
  - Demonstration of true lumen with flow and false (thrombosed) lumen without flow; unlike veins, true and false lumens are noncompressible by probe pressure; flow in false lumen resulting from more distal reentry into true lumen, as frequently found in CCA dissection associated with dissecting aortic aneurysm,[31-34] is rare
  - Axial sections show "membrane" as flap in lumen
- Findings at follow-up examinations
  - Recovery of lumen patency
  - Flow recovery
  - Recovery of normal hemodynamics, when combined with TCD

*ICA indicates internal carotid artery; CCA, common carotid artery; and TCD, transcranial Doppler sonography.

Table 5.—Limitations of Duplex Sonography

- Anatomic
  - Short and / or fat neck, high cervical carotid bifurcation, goiter, calcification of atherosclerotic lesions (sound shadow)
- Individual
  - Restless, agitated, continuously swallowing patients, air emphysema; direct examination may be impossible
- Methodic
  - Occlusion cannot always be demonstrated directly because of its high cervical location
  - Usually, whole longitudinal extension of wall dissection and especially involvement of intracranial ICA segments (occurring in up to 20%[39,40]) cannot be detected
  - Detection of aneurysms is usually not possible[29]
  - Identification of fibromuscular dysplasia as underlying cause[16,39] is hardly ever possible

ultrasound, direct visualization of the ICD is not possible in all cases.[22]

Sensitivity of CUE in detecting occlusion in the case of ICD was very high in one study (95%).[22] Its emergency use in cases where clinical presentation suggests dissection does help in rapid diagnosis and selection of patients for angiography.

Duplex sonography has several methodologic limitations, listed in Table 5. These are the major reasons why I still consider angiography to be necessary to assess the full extent of the vascular process and to confirm the ultrasound findings.

In addition to its use in initial diagnosis, duplex scanning is an excellent noninvasive modality for serial follow-up examination.[29,35,36] The signs indicating recovery are listed in Table 4. Spontaneous resolution or reduction of stenosis may occur at variable intervals, ranging from a few days to several months.[19,22,29] Sequential follow-up studies have shown that this process generally occurs within a few days and only occasionally over weeks or months.[3,29,35,37-39]

Most authors agree that ischemic infarction is due in most cases to distal embolism from local thrombosis at the stenotic segment. The role of embolism is evident from the occurrence of ischemic symptoms when a stenosis is hemodynamically insignificant, from arteriography that shows distal emboli, and from intraluminal thrombus seen arteriographically and at surgery. Embolic stroke may develop in the first few days of dissection,* and its frequency is estimated to be at least 15%[3] to 24%.[21] Moreover, stenosis may progress to occlusion,[17,18,40] resulting in a critical hemodynamic situation and preventing recanalization. These potential complications are the reason why anticoagulant therapy, first with heparin, is recommended by several authors[2,42] with the idea to prevent thrombosis and embolism. It is logical that treatment should be started as early as possible, implicating early diagnosis, facilitated by application of CUE. As controlled studies are lacking, the efficacy of such therapy remains unproved, regardless of the nature and degree of the anatomic disease present. To date, no harmful effect of anticoagulant therapy, including cases with extracranial aneurysms, has been reported,[2,8,11,17,22,42] and only the simultaneous presence of an intracranial aneurysm is considered a contraindication.[2] Several uncontrolled studies suggest beneficial effects of anticoagulation.[21,22,43] On the other hand, it seems pointless to continue anticoagulant therapy once vascular patency has been restored. The CUE offers the possibility of noninvasive follow-up to detect the moment of recanalization. As spontaneous recanalization is the rule,[2-4,17,22,37,44-46] surgical interventions remain exceptional[2-4,8,37,47,48] and are reserved for patients with recurrent or progressive ischemic symptoms despite anticoagulant therapy. If these ischemic symptoms are due to insufficient collateral blood supply, it may be detected by TCD (case 5). Therefore, TCD may help in selecting patients for revascularization procedures.

In conclusion, CUE with special emphasis on duplex scanning is particularly useful to select patients with suspected ICD for arteriography and thus provides a tool for early diagnosis by its emergency use. It is the method of choice for follow-up examinations to determine duration of anticoagulation and may help to assess the real frequency of ICD when also used in patients in whom angiography would not be considered.

I wish to thank Peter Huber, director of the Department of Neuroradiology, University of Bern, Switzerland, for performing the neuroradiologic examinations.

Millions Go Widely Untreated

A Depression Teleconference sponsored by the American Medical Association and the National Institute of Mental Health

According to the National Institute of Mental Health, over 10 million Americans will suffer from depression at least once in their lives.

Most patients are not seen by mental health professionals, but by primary care physicians.

The American Medical Association and the National Institute of Mental Health are sponsoring a three-part teleconference at *no cost* to you, offering the primary care physician important information on diagnosing and treating depression among patients.

You are invited, and encouraged, to attend this important series. There will be numerous satellite link-ups at hospitals throughout the United States. Call now to register and to find out the location nearest you.

Schedule:

Program One: **Epidemiology, Etiology, Diagnosis**
October 24, 1991
2:00-3:30 pm (ET)

Program Two: **Treatment: Pharmacology and Psychotherapy**
November 21, 1991
2:00-3:30 pm (ET)

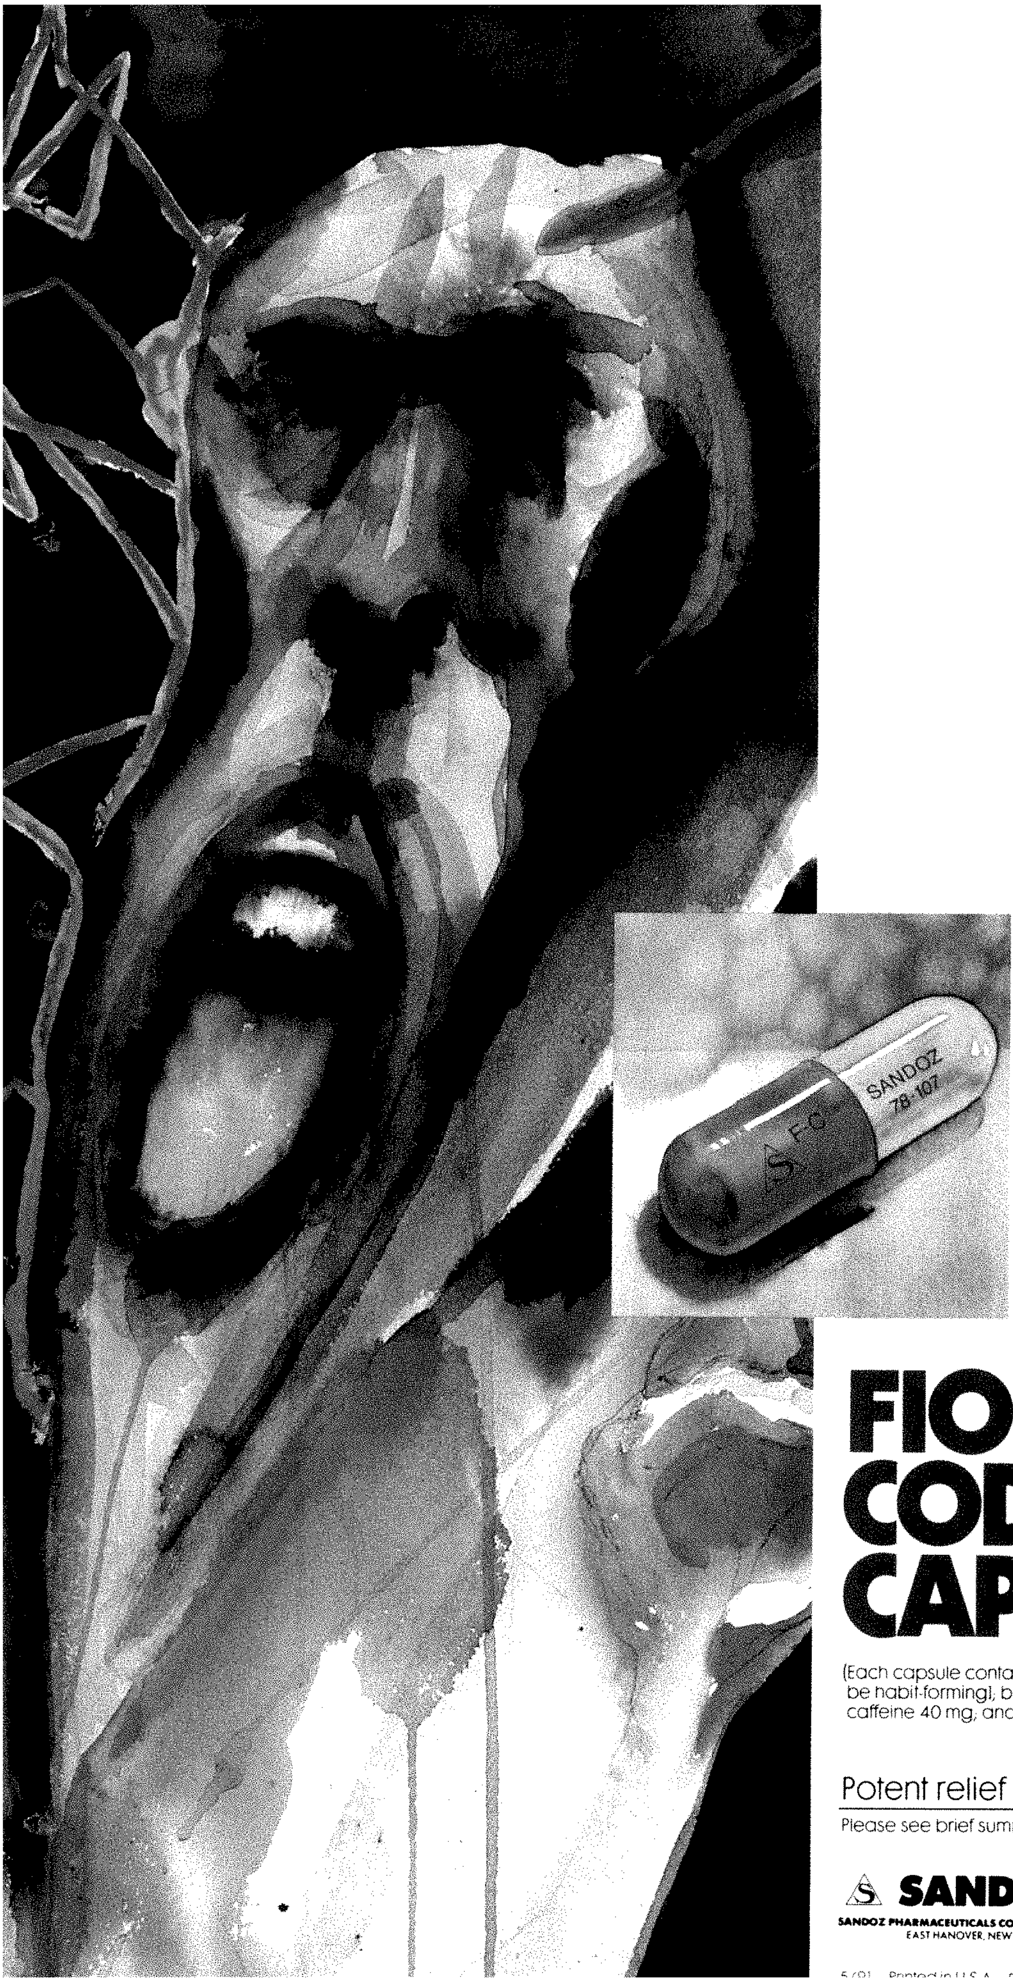
Program Three: **Depression Among Special Populations**
December 11, 1991
2:00-3:30 pm (ET)

To register for this *free* teleconference and to find out the location nearest you, call TOLL-FREE 1-800-262-3211.

The American Medical Association is accredited by the Accreditation Council for Continuing Medical Education to sponsor continuing medical education for physicians. The American Medical Association designates this continuing medical education activity for 1.5 credit hours of Category 1 of the Physician's Recognition Award of the American Medical Association.

This program has been reviewed and is acceptable for 1.5 prescribed hours by the American Academy of Family Physicians.

The American College of Obstetricians and Gynecologists has assigned 2 cognates (formal learning) to this program.



HEADACHE DESCRIBED

"Headache"– a personal interpretation of headache pain by John Crowley, a headache patient.

HEADACHE RELIEVED

Effectively treats the pain of muscle contraction headache as well as the anxiety and tension that magnify it

FIORINAL® WITH CODEINE CAPSULES Ⓒ III

(Each capsule contains: codeine phosphate 30 mg [Warning: May be habit-forming]; butalbital 50 mg [Warning: May be habit-forming]; caffeine 40 mg; and aspirin 325 mg)

Potent relief of tension headache pain

Please see brief summary on following page.

SANDOZ

SANDOZ PHARMACEUTICALS CORPORATION
EAST HANOVER, NEW JERSEY 07936

5/91 Printed in U.S.A. [illegible]

BRIEF SUMMARY: Please see package insert for full prescribing information.

FIORINAL® WITH CODEINE CIII CAPSULES

(Codeine phosphate USP, 30 mg [warning: may be habit forming], butalbital USP, 50 mg [warning: may be habit forming]; caffeine USP, 40 mg; aspirin USP, 325 mg)

CAUTION: Federal law prohibits dispensing without prescription.

CONTRAINDICATIONS: Fiorinal® with Codeine is contraindicated under the following conditions:

1. Hypersensitivity or intolerance to aspirin, caffeine, butalbital or codeine.
2. Patients with a hemorrhagic diathesis (e.g., hemophilia, hypoprothrombinemia, von Willebrand's disease, the thrombocytopenias, thrombasthenia and other ill-defined hereditary platelet dysfunctions, severe vitamin K deficiency and severe liver damage.)
3. Patients with the syndrome of nasal polyps, angioedema and bronchospastic reactivity to aspirin or other nonsteroidal anti-inflammatory drugs. Anaphylactoid reactions have occurred in such patients.
4. Peptic ulcer or other serious gastrointestinal lesions.
5. Patients with porphyria.

WARNINGS: Therapeutic doses of aspirin can cause anaphylactic shock and other severe allergic reactions. It should be ascertained if the patient is allergic to aspirin, although a specific history of allergy may be lacking.

Significant bleeding can result from aspirin therapy in patients with peptic ulcer or other gastrointestinal lesions, and in patients with bleeding disorders.

Aspirin administered pre-operatively may prolong the bleeding time.

In the presence of head injury or other intracranial lesions, the respiratory depressant effects of codeine and other narcotics may be markedly enhanced, as well as their capacity for elevating cerebrospinal fluid pressure. Narcotics also produce other CNS depressant effects, such as drowsiness, that may further obscure the clinical course of patients with head injuries.

Codeine or other narcotics may obscure signs on which to judge the diagnosis or clinical course of patients with acute abdominal conditions.

Butalbital and codeine are both habit-forming and potentially abusable. Consequently, the extended use of Fiorinal® with Codeine is not recommended.

Results from epidemiologic studies indicate an association between aspirin and Reye Syndrome. Caution should be used in administering this product to children, including teenagers, with chicken pox or flu.

PRECAUTIONS: General: Fiorinal® with Codeine should be prescribed with caution for certain special-risk patients such as the elderly or debilitated, and those with severe impairment of renal or hepatic function, coagulation disorders, or head injuries.

Aspirin should be used with caution in patients on anticoagulant therapy and in patients with underlying hemostatic defects.

Precautions should be taken when administering salicylates to persons with known allergies. Hypersensitivity to aspirin is particularly likely in patients with nasal polyps, and relatively common in those with asthma.

Information for Patients: Patients should be informed that Fiorinal® with Codeine contains aspirin and should not be taken by patients with an aspirin allergy.

Fiorinal® with Codeine may impair the mental and/or physical abilities required for performance of potentially hazardous tasks such as driving a car or operating machinery. Such tasks should be avoided while taking Fiorinal® with Codeine.

Alcohol and other CNS depressants may produce an additive CNS depression when taken with Fiorinal® with Codeine, and should be avoided.

Codeine and butalbital may be habit-forming. Patients should take the drug only for as long as it is prescribed, in the amounts prescribed, and no more frequently than prescribed.

Laboratory Tests: In patients with severe hepatic or renal disease, effects of therapy should be monitored with serial liver and/or renal function tests.

Drug Interactions: The CNS effects of butalbital may be enhanced by monoamine oxidase (MAO) inhibitors.

In patients receiving concomitant corticosteroids and chronic use of aspirin, withdrawal of corticosteroids may result in salicylism because corticosteroids enhance renal clearance of salicylates and their withdrawal is followed by return to normal rates of renal clearance.

Fiorinal® with Codeine may enhance the effects of:

1. Oral anticoagulants, causing bleeding by inhibiting prothrombin formation in the liver and displacing anticoagulants from plasma protein binding sites.
2. Oral antidiabetic agents and insulin, causing hypoglycemia by contributing an additive effect, if dosage of Fiorinal® with Codeine exceeds maximum recommended daily dosage.
3. 6-mercaptopurine and methotrexate, causing bone marrow toxicity and blood dyscrasias by displacing these drugs from secondary binding sites, and, in the case of methotrexate, also reducing its excretion.
4. Non-steroidal anti-inflammatory agents, increasing the risk of peptic ulceration and bleeding by contributing additive effects.
5. Other narcotic analgesics, alcohol, general anesthetics, tranquilizers such as chlordiazepoxide, sedative-hypnotics, or other CNS depressants, causing increased CNS depression.

Fiorinal® with Codeine may diminish the effects of: Uricosuric agents such as probenecid and sulfinpyrazone, reducing their effectiveness in the treatment of gout. Aspirin competes with these agents for protein binding sites.

Drug/Laboratory Test Interactions

Aspirin: Aspirin may interfere with the following laboratory determinations in blood: serum amylase, fasting blood glucose, cholesterol, protein, serum glutamic-oxalacetic transaminase (SGOT), uric acid, prothrombin time and bleeding time. Aspirin may interfere with the following laboratory determinations in urine: glucose, 5-hydroxyindoleacetic acid, Gerhardt ketone, vanillylmandelic acid (VMA), uric acid, diacetic acid, and spectrophotometric detection of barbiturates.

Codeine: Codeine may increase serum amylase levels.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Adequate long-term studies have been conducted in mice and rats with aspirin, alone or in combination with other drugs, in which no evidence of carcinogenesis was seen. No adequate studies have been conducted in animals to determine whether aspirin has a potential for mutagenesis or impairment of fertility. No adequate studies have been conducted in animals to determine whether butalbital has a potential for carcinogenesis, mutagenesis, or impairment of fertility.

Usage in Pregnancy

Teratogenic Effects: Pregnancy Category C — Animal reproduction studies have not been conducted with Fiorinal® with Codeine. It is also not known whether Fiorinal® with Codeine can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Fiorinal® with Codeine should be given to a pregnant woman only when clearly needed.

Nonteratogenic Effects: Although Fiorinal® with Codeine was not implicated in the birth defect, a female infant was born with lissencephaly, pachygyria and heterotopic gray matter. The infant was born 8 weeks prematurely to a woman who had taken an average of 90 Fiorinal® with Codeine capsules each month from the first few days of pregnancy. The child's development was mildly delayed and from one year of age she had partial simple motor seizures.

Withdrawal seizures were reported in a two-day-old male infant whose mother had taken a butalbital-containing drug during the last 2 months of pregnancy. Butalbital was found in the infant's serum. The infant was given phenobarbital 5mg/kg, which was tapered without further seizure or other withdrawal symptoms.

Studies of aspirin use in pregnant women have not shown that aspirin increases the risk of abnormalities when administered during the first trimester of pregnancy. In controlled studies involving 41,337 pregnant women and their offspring, there was no evidence that aspirin taken during pregnancy caused stillbirth, neonatal death or reduced birth weight. In controlled studies of 50,282 pregnant women and their offspring, aspirin administration in moderate and heavy doses during the first four lunar months of pregnancy showed no teratogenic effect.

Reproduction studies have been performed in rabbits and rats at doses up to 150 times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to codeine.

Therapeutic doses of aspirin in pregnant women close to term may cause bleeding in mother, fetus, or neonate. During the last 6 months of pregnancy, regular use of aspirin in high doses may prolong pregnancy and delivery.

Labor and Delivery: Ingestion of aspirin prior to delivery may prolong delivery or lead to bleeding in the mother or neonate. Use of codeine during labor may lead to respiratory depression in the neonate.

Nursing Mothers: Aspirin, caffeine, barbiturates and codeine are excreted in breast milk in small amounts, but the significance of their effects on nursing infants is not known. Because of potential for serious adverse reactions in nursing infants from Fiorinal® with Codeine, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use: Safety and effectiveness in children below the age of 12 have not been established.

ADVERSE REACTIONS: Commonly Observed: The most commonly reported adverse events associated with the use of Fiorinal® with Codeine and not reported at an equivalent incidence by placebo-treated patients were nausea and/or abdominal pain, drowsiness, and dizziness.

Associated with Treatment Discontinuation: Of the 382 patients treated with Fiorinal® with Codeine in controlled clinical trials, three (0.8%) discontinued treatment with Fiorinal® with Codeine because of adverse events. One patient each discontinued treatment for the following reasons: gastrointestinal upset; lightheadedness and heavy eyelids; and drowsiness and generalized tingling.

Incidence in Controlled Clinical Trials: The following table summarizes the incidence rates of the adverse events reported by at least 1% of the Fiorinal® with Codeine treated patients in controlled clinical trials comparing Fiorinal® with Codeine to placebo, and provides a comparison to the incidence rates reported by the placebo-treated patients.

The prescriber should be aware that these figures cannot be used to predict the incidence of side effects in the course of usual medical practice where patient characteristics and other factors differ from those that prevailed in the clinical trials. Similarly, the cited frequencies cannot be compared with figures obtained from other clinical investigations involving different treatments, uses, and investigators.

Adverse Events Reported by at Least 1% of Fiorinal® with Codeine Treated Patients During Placebo Controlled Clinical Trials

	Incidence Rate of Adverse Events	
Body System/ Adverse Event	Fiorinal®/Codeine (N = 382)	Placebo (N = 377)
Central Nervous		
Drowsiness	2.4%	0.5%
Dizziness/Lightheadedness	2.6%	0.5%
Intoxicated Feeling	1.0%	0%
Gastrointestinal		
Nausea/Abdominal Pain	3.7%	0.8%

Other Adverse Events Reported During Controlled Clinical Trials: The listing that follows represents the proportion of the 382 patients exposed to Fiorinal® with Codeine while participating in the controlled clinical trials who reported, on at least one occasion, an adverse event of the type cited. All reported adverse events, except those already presented in the previous table, are included. It is important to emphasize that, although the adverse events reported did occur while the patient was receiving Fiorinal® with Codeine, the adverse events were not necessarily caused by Fiorinal® with Codeine.

Adverse events are classified by body system and frequency. "Frequent" is defined as an adverse event which occurred in at least 1/100 (1%) of the patients; all adverse events listed in the previous table are frequent. "Infrequent" is defined as an adverse event that occurred in less than 1/100 patients but at least 1/1000 patients. All adverse events tabulated below are classified as infrequent.

Central Nervous: headache, shaky feeling, tingling, agitation, fainting, fatigue, heavy eyelids, high energy, hot spells, numbness, and sluggishness.

Autonomic Nervous: dry mouth and hyperhidrosis.

Gastrointestinal: vomiting, difficulty swallowing, and heartburn.

Cardiovascular: tachycardia.

Musculoskeletal: leg pain and muscle fatigue.

Genitourinary: diuresis.

Miscellaneous: pruritus, fever, earache, nasal congestion, and tinnitus.

Voluntary reports of adverse drug events, temporally associated with Fiorinal® with Codeine, that have been received since market introduction and that were not reported in clinical trials by the patients treated with Fiorinal® with Codeine, are listed below. Many or most of these events may have no causal relationship with the drug and are listed according to body system.

Central Nervous: Abuse, addiction, anxiety, depression, disorientation, hallucination, hyperactivity, insomnia, libido decrease, nervousness, neuropathy, psychosis, sedation, sexual activity increase, slurred speech, twitching, unconsciousness, vertigo.

Autonomic Nervous: epistaxis, flushing, miosis, salivation.

Gastrointestinal: anorexia, appetite increased, constipation, diarrhea, esophagitis, gastroenteritis, gastrointestinal spasm, hiccup, mouth burning, pyloric ulcer.

Cardiovascular: chest pain, hypotensive reaction, palpitations, syncope.

Skin: erythema, erythema multiforme, exfoliative dermatitis, hives, rash, toxic epidermal necrolysis.

Urinary: kidney impairment, urinary difficulty.

Miscellaneous: allergic reaction, anaphylactic shock, cholangiocarcinoma, drug interaction with erythromycin (stomach upset), edema.

The following adverse drug events may be borne in mind as potential effects of the components of Fiorinal® with Codeine. Potential effects of high dosage are listed in the *OVERDOSAGE* section of this insert.

Asprin: occult blood loss, hemolytic anemia, iron deficiency anemia, gastric distress, heartburn, nausea, peptic ulcer, prolonged bleeding time, acute airway obstruction, renal toxicity when taken in high doses for prolonged periods, impaired urate excretion, hepatitis.

Caffeine: cardiac stimulation, irritability, tremor, dependence, nephrotoxicity, hyperglycemia.

Codeine: nausea, vomiting, drowsiness, lightheadedness, constipation, pruritus.

DRUG ABUSE AND DEPENDENCE: Fiorinal® with Codeine is controlled by the Drug Enforcement Administration and is classified under Schedule III.

Codeine: Codeine can produce drug dependence of the morphine type and, therefore, has the potential for being abused. Psychological dependence, physical dependence, and tolerance may develop upon repeated administration and it should be prescribed and administered with the same degree of caution appropriate to the use of other oral narcotic medications.

Butalbital: *Barbiturates may be habit forming:* Tolerance, psychological dependence, and physical dependence may occur especially following prolonged use of high doses of barbiturates. The average daily dose for the barbiturate addict is usually about 1,500 mg. As tolerance to barbiturates develops, the amount needed to maintain the same level of intoxication increases; tolerance to a fatal dosage, however, does not increase more than two-fold. As this occurs, the margin between an intoxication dosage and fatal dosage becomes smaller. The lethal dose of a barbiturate is far less if alcohol is also ingested. Major withdrawal symptoms (convulsions and delirium) may occur within 16 hours and last up to 5 days after abrupt cessation of these drugs. Intensity of withdrawal symptoms gradually declines over a period of approximately 15 days. Treatment of barbiturate dependence consists of cautious and gradual withdrawal of the drug. Barbiturate-dependent patients can be withdrawn by using a number of different withdrawal regimens. One method involves initiating treatment at the patient's regular dosage level and gradually decreasing the daily dosage as tolerated by the patient.

OVERDOSAGE: The toxic effects of acute overdosage of Fiorinal® with Codeine capsules are attributable mainly to the barbiturate and codeine components, and, to a lesser extent, aspirin. Because toxic effects of caffeine occur in very high dosages only, the possibility of significant caffeine toxicity from Fiorinal® with Codeine overdosage is unlikely.

Signs and Symptoms: Symptoms attributable to *acute barbiturate poisoning* include drowsiness, confusion, and coma; respiratory depression; hypotension; shock. Symptoms attributable to *acute aspirin poisoning* include hyperpnea, acid-base disturbances with development of metabolic acidosis, vomiting and abdominal pain; tinnitus, hyperthermia; hypoprothrombinemia; restlessness; delirium; convulsions. *Acute caffeine poisoning* may cause insomnia, restlessness, tremor, and delirium; tachycardia and extrasystoles. Symptoms of *acute codeine poisoning* include the triad of: pinpoint pupils, marked depression of respiration, and loss of consciousness. Convulsions may occur.

Treatment: The following paragraphs describe one approach to the treatment of overdose with Fiorinal® with Codeine. However, because strategies for the management of an overdose continually evolve, consultation with a regional poison control center is strongly encouraged.

Treatment consists primarily of management of barbiturate intoxication, reversal of the effects of codeine, and the correction of the acid-base imbalance due to salicylism. Vomiting should be induced mechanically or with emetics in the conscious patient. Gastric lavage may be used if the pharyngeal and laryngeal reflexes are present and if less than 4 hours have elapsed since ingestion. A cuffed endotracheal tube should be inserted before gastric lavage of the unconscious patient and when necessary to provide assisted respiration. Diuresis, alkalinization of the urine, and correction of electrolyte disturbances should be accomplished through administration of intravenous fluids such as 1% sodium bicarbonate and 5% dextrose in water.

Meticulous attention should be given to maintaining adequate pulmonary ventilation. Correction of hypotension may require the administration of levarterenol bitartrate or phenylephrine hydrochloride by intravenous infusion. In severe cases of intoxication, peritoneal dialysis, hemodialysis, or exchange transfusion may be lifesaving. Hypoprothrombinemia should be treated with vitamin K, intravenously.

Methemoglobinemia over 30% should be treated with methylene blue by slow intravenous administration.

Naloxone, a narcotic antagonist, can reverse respiratory depression and coma associated with opioid overdose. Typically, a dose of 0.4 mg to 2 mg is given parenterally and may be repeated if an adequate response is not achieved. Since the duration of action of codeine may exceed that of the antagonist, the patient should be kept under continued surveillance and repeated doses of the antagonist should be administered as needed to maintain adequate respiration. A narcotic antagonist should not be administered in the absence of clinically significant respiratory or cardiovascular depression.

Toxic and Lethal Doses:

Butalbital: toxic dose 1.0 g (adult); lethal dose 2.0-5.0 g
Aspirin: toxic blood level greater than 30 mg/100 mL; lethal dose 10-30 g (adult)
Caffeine: toxic dose greater than 1.0 g; lethal dose unknown
Codeine: lethal dose 0.5-1.0 g (adult)

High-Intensity Area in the Deep White Matter Indicating Hemodynamic Compromise in Internal Carotid Artery Occlusive Disorders

Hiroshi Yamauchi, MD; Hidenao Fukuyama, MD; Shinya Yamaguchi, MD;
Toshihiko Miyoshi, MD; Jun Kimura, MD; Junji Konishi, MD

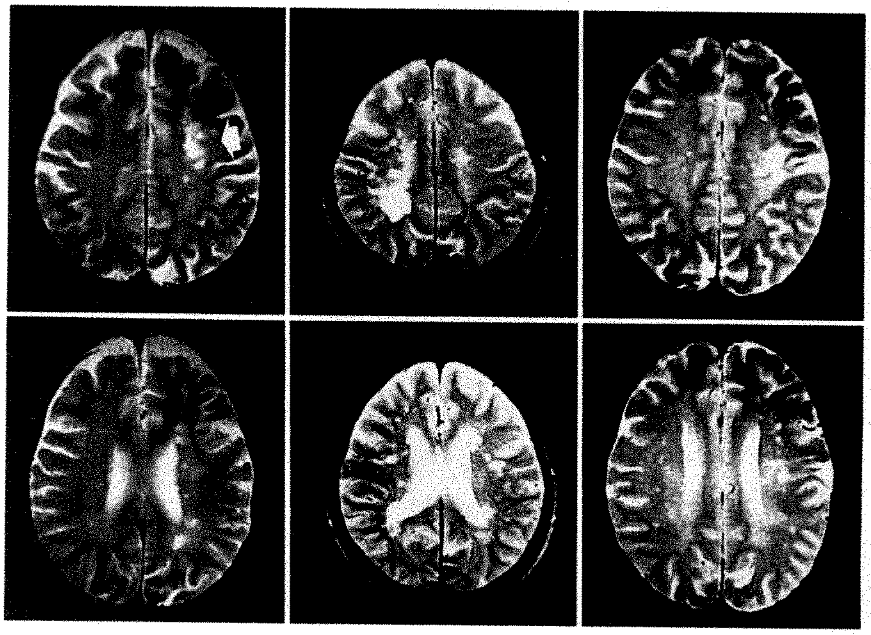
• We used positron emission tomography and magnetic resonance imaging to evaluate 16 patients with transient ischemic attacks or minor strokes and unilateral internal carotid occlusive disease, five with stenosis, and 11 with occlusion. Cerebral blood flow, cerebral metabolic rate of oxygen, oxygen extraction fraction, cerebral blood volume, and T_2-weighted magnetic resonance images obtained at 1.5-T were analyzed. Irrespective of vascular disease, patients with a confluent high-intensity area in the middle centrum semiovale had substantially decreased cerebral blood flow and ratio of cerebral blood flow to blood volume in the middle cerebral artery distribution of the cortex, with a substantially increased oxygen extraction fraction. We concluded that the confluent high-intensity area in the deep white matter region indicates hemodynamic compromise in the affected hemisphere in internal carotid artery occlusive disease.

(*Arch Neurol.* 1991;48:1067-1071)

Magnetic resonance imaging (MRI), especially T_2-weighted images, has been found to be very sensitive in the detection of cerebral white matter disease.[1] However, whether high signal intensity in the periventricular or paraventricular regions on T_2-weighted images may indicate a pathologic state or may be of no importance remains uncertain.[2]

Hypoperfusion secondary to internal carotid artery (ICA) occlusion often results in cerebral infarction involving the deep white matter, especially the watershed zone between the distribution of the anterior cerebral artery and middle cerebral artery (MCA), with sparing of the cortical surface.[3-6] This may be because the subcortical watershed zone supplied by the most distal branches of the cortical perforating arteries is most susceptible to a reduction in perfusion pressure,[7] although the regional differences in the capacity for collateral vessel blood supply must be considered.[8] This speculation supports the hypothesis that ischemic change in the middle centrum semiovale, the most distal white matter region supplied by the

Fig 1.—Examples of high-intensity lesions on T_2-weighted magnetic resonance images (repetition time, 2000 msec; echo time, 80 msec). Left, Confluent high-intensity area in the middle centrum semiovale (arrow) in patient 13. Middle, Immediate subcortical patchy high-intensity area in patient 8. Right, Immediate subcortical punctate high-intensity areas in patient 2. Upper and lower rows correspond to the levels of the centrum semiovale and the body of the lateral ventricle, respectively.



Accepted for publication March 12, 1991.

ICA, indicates hemodynamic compromise in the affected hemisphere in carotid occlusive diseases.

Our purpose was to evaluate the relationship between the cortical hemodynamic status and the presence of a white matter high-intensity area on MRI in carotid occlusive disease and to examine the high-intensity area as a sign of hemodynamic compromise.

PATIENTS AND METHODS

Patients

Our study involved 16 patients with unilateral ICA occlusive disease, five with stenosis (>70% diameter reduction) and 11 with occlusion. Neurologic histories of the 16 patients consisted of eight with transient ischemic attacks and eight with minor completed strokes, all related to the affected carotid distribution. Our criteria for selection were as follows; (1) In all patients with ICA stenosis (ICS), the carotid artery distribution of the affected hemisphere was perfused through the stenosed carotid artery proper on angiography. All patients with ICA occlusion (ICO) had collateral vessel circulation through the anterior portion of the circle of Willis. In these two categories of carotid artery disease, the centrum semiovale is the most distal white matter area perfused by the stenosed carotid artery or the collateral vessel circulation through the anterior communicating artery. (2) All patients had, at most, only minor subcortical abnormalities (<1.5 cm in diameter) in the region supplied by the MCA on the side involved by carotid artery disease on computed tomography (CT).

Positron Emission Tomographic (PET) Measurement

Specifications of our PET scanner have been reported elsewhere.[9] In brief, it consists of four rings of 192 bismuth germanate detectors, providing seven slices with each scan. The device offers the best spatial resolution of 7.6 mm in full width half maximum at the center of the scan field and axial resolution of 12 mm at the center. Blood was sampled through cannulation of the brachial artery three times during a scanning process to determine oxygen 15 activity and arterial blood gases. Before the study, transmission scanning with germanium 68-gallium 68 was performed for 20 minutes for attenuation correction. We determined calibration factors between the PET scanner and the well counter in every study, as well as the calibration factor of cross-planes of the PET scanner. A dead time correction and a scatter correction were performed on obtained data. Image data were processed with an image processing computer (Hitachi Medical Co, Tokyo, Japan) with the use of system subroutines to reconstruct functional images constituting 64 × 64 pixels, each pixel representing 2.5 × 2.5 mm.

Cerebral blood flow (CBF) was determined while the patient was continuously inhaling ^{15}O-labeled carbon dioxide (370 to 555 MBq per minute) through a mask. Measurement of the cerebral metabolic rate of oxygen ($CMRO_2$) and oxygen extraction fraction (OEF) of the brain required continuous inhalation of ^{15}O-labeled oxygen at 740 to 1110 MBq per minute. Scan data were collected for 5 minutes. A single breath of ^{15}O-labeled carbon monoxide (2960 MBq) was used to measure cerebral blood volume (CBV). Calculation of CBF, $CMRO_2$, and OEF was based on the steady-state method,[10] and $CMRO_2$ and OEF were corrected by the CBV.[11]

Positron emission tomography was performed at least 1 month after the latest ischemic event in all patients.

MRI

After PET scanning, MRI (Signa, General Electric, Milwaukee, Wis; 1.5 T) was performed. T_2- and T_1-weighted images were obtained with a spin-echo sequence with a repetition time of 2000 msec and an echo time of 80 msec and a repetition time of 400 msec and an echo time of 20 msec, respectively. Magnetic resonance images were obtained as closely as possible and parallel to the scan plane of the PET images. Slice thickness was 3 mm, with a 2-mm interslice gap.

Data Analysis

Patients with ICO were divided into two subgroups, based on the presence or absence of a high-intensity area in the middle centrum semiovale of the occluded hemisphere on T_2-weighted images. The high-intensity area was a confluent area far from the cerebral cortex and ventricular wall, extending along the dorsolateral aspect of the lateral ventricle (arrow in Fig 1, top left). These abnormalities were usually undetectable on CT and T_1-weighted images. No patients with ICS had this high-intensity area. Patients without this high-intensity area had punctate or patchy, or linear, high-intensity areas in the immediate subcortical or periventricular white matter (Fig 1, middle and

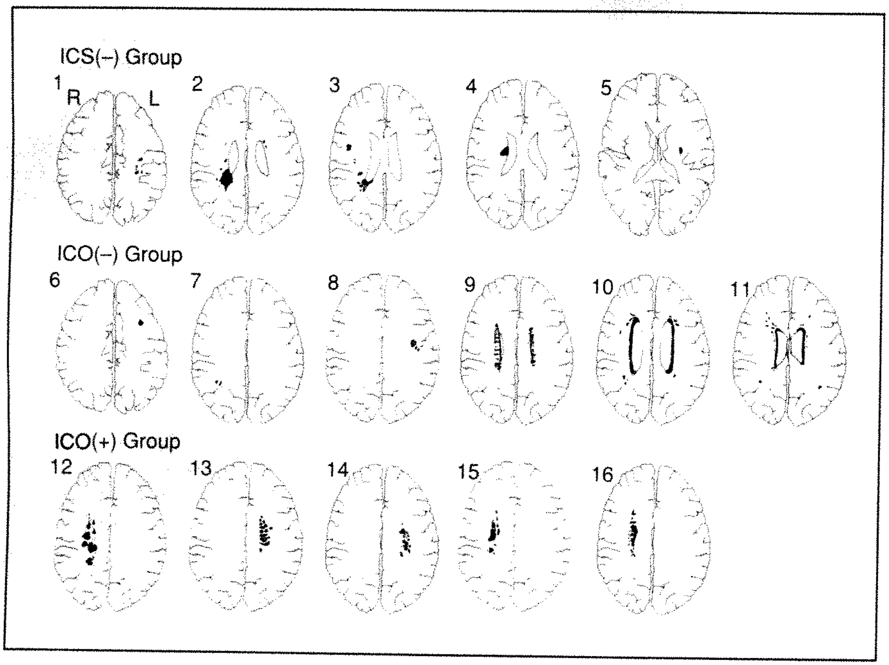

Fig 2.—Distribution of the high-intensity areas on T_2-weighted magnetic resonance images in the three patient groups. Numbers are patient numbers, as listed in Table 1. ICS(–) indicates patients with stenosis without the high-intensity area in the middle centrum semiovale; ICO(–), patients with occlusion without this high-intensity area; and ICO(+), patients with occlusion with this high-intensity area.

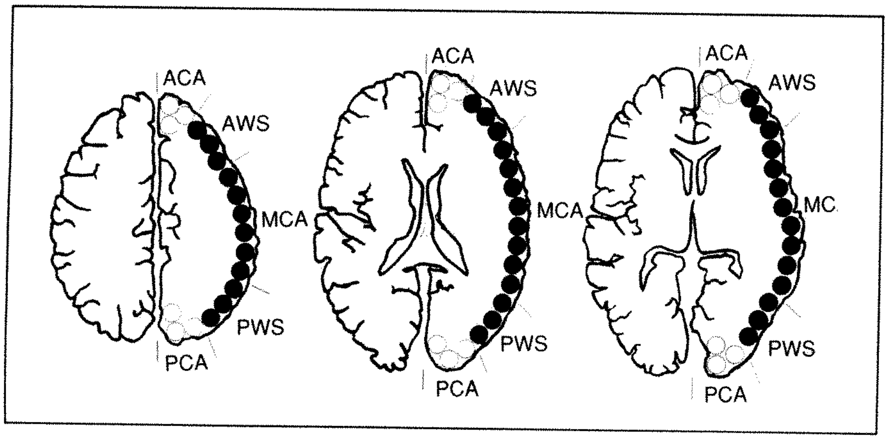

Fig 3.—Three diagrams illustrating circular regions of interest, placed over the cerebral cortex divided into five areas: territories supplied by the anterior cerebral artery (ACA), middle cerebral artery (MCA), and posterior cerebral artery (PCA), as well as the watershed areas between the ACA and MCA (anterior watershed [AWS]) and the MCA and PCA (posterior watershed [PWS]). A hemispheric value was calculated as the average of the MCA, AWS, and PWS in the affected hemisphere (solid circles), weighted by region size.

right). The study patients were then divided into three subgroups: group ICS(–) (n = 5; mean age, 63.2 years) included patients with stenosis without this high-intensity area in the middle centrum semiovale (Fig 1, middle); group ICO(–) (n = 6; mean age, 62.3 years) included patients with occlusion without this high-intensity area (Fig 1, right); and group ICO(+) (n = 5; mean age, 55.2 years) included patients with occlusion with this high-intensity area (Fig 1, left). Clinical and neuroradiologic data on patients in the three groups are summarized in Table 1. Distributions of the high-intensity areas in all cases are illustrated in Fig 2.

We analyzed three tomographic planes—4.0, 6.6, and 8.2 cm above and parallel to the orbitomeatal line. These corresponded to the levels of the basal ganglia and thalamus, the body of the lateral ventricle, and the centrum semiovale. Each image was examined by placing a total of 18 to 20 circular regions of interest, each containing 11 pixels (0.785 cm^2), over the gray matter of the cortex (Fig 3). According to the atlas by Kretschmann and Weinrich,[12] the regions of interest in all three images were included in the distribution of the anterior cerebral artery, MCA, and posterior cerebral artery, as well as the watershed areas between anterior cerebral artery and MCA (anterior watershed) and the MCA and posterior cerebral artery (posterior watershed). A hemispheric value was calculated as the average of the MCA, anterior watershed, and posterior watershed in the affected hemisphere, weighted by region size.

Hemispheric values from the three patient groups were compared with analysis of variance with Bonferroni's t test, with differences yielding $P<.05$ regarded as significant.

RESULTS

The physiologic states of the three patient groups during PET scanning are described in Table 2, including arterial hemoglobin concentration, hematocrit, Pa_{O_2}, Pa_{CO_2}, and mean arterial blood pressure.

Figure 4 shows the hemispheric values for regional CBF, $CMRO_2$, OEF, CBV, and CBF/CBV for each patient in the three groups. Patients with ICO and the high-intensity area in the middle centrum semiovale (ICO[+] group) had significantly ($P<.01$) decreased CBF and CBF/CBV, with significantly ($P<.05$) elevated OEF, compared with the other two groups. The $CMRO_2$ reduction was significant only when compared with the ICS(–) group. A difference in CBF only was present between the ICO(–) and ICS(–) groups.

COMMENT

The high prevalence of subcortical high-intensity areas on T_2-weighted images in the elderly makes its clinical significance obscure.[2] The high intensities include such abnormalities as état criblé, atrophic perivascular demyelination, gliosis, myelin pallor, demyelination, edema, and infarction.[2] In ICO, high-intensity areas on T_2-weighted images are considered to be a result of ischemic changes. Computed tomography and T_1-weighted images do not detect corresponding abnormalities, implying that the high-intensity areas in the T_2-weighed images do not indicate complete infarctions with cavitation but only mild or early ischemic changes. Magnetic resonance imaging is able to detect the abnormalities at an early stage, before severe ischemic damage develops.

Stained or striated hypodense areas in the parietal white matter on CT, mostly in the supraventricular region, have been reported to be a typical finding in cases of stenosis or occlusion of the carotid artery.[3] Another study[5] involving MRI also reported that unilateral high-intensity areas in the deep watershed zone on T_2-weighted images were frequently associated with substantial carotid stenosis, defined as greater than 80%. The watershed in-

Table 2.—Baseline Physiologic Data on Patients in the Three Groups*

Factor	ICS(−)	ICO(−)	ICO(+)
Pa_{CO_2}, mm Hg	43.8 ± 7.0	38.6 ± 10.3	43.0 ± 1.1
Pa_{O_2}, mm Hg	86.0 ± 7.5	86.8 ± 7.0	84.6 ± 7.7
Hematocrit	0.369 ± 0.043	0.378 ± 0.045	0.412 ± 0.021

MABP, mm Hg	99.1 ± 14.1	100.4 ± 12.5	98.7 ± 13.6

*Values are mean ± SD. MABP indicates mean arterial blood pressure. There was no difference among the three groups, which are explained in the text and in Table 1.

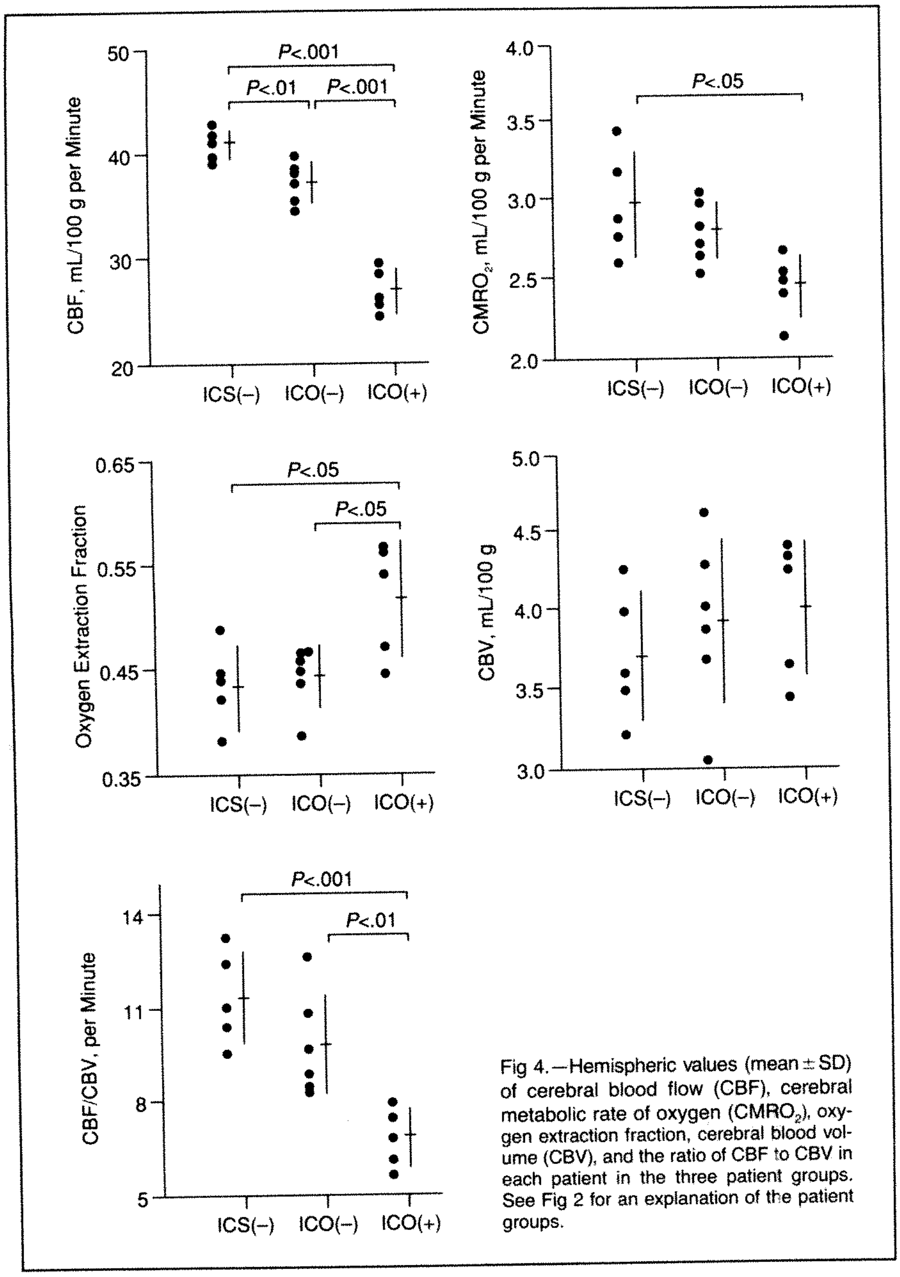

Fig 4.—Hemispheric values (mean ± SD) of cerebral blood flow (CBF), cerebral metabolic rate of oxygen ($CMRO_2$), oxygen extraction fraction, cerebral blood volume (CBV), and the ratio of CBF to CBV in each patient in the three patient groups. See Fig 2 for an explanation of the patient groups.

farctions in ICO are derived from various pathogeneses.[13,14] Among them, deep watershed infarction has been believed to be hemodynamic.[4,6,8,15] Internal carotid artery occlusion with adequate anterior circle of Willis anastomosis, such as in our patients, has often been associated with this type of hemodynamically induced infarction.[16] The middle centrum semiovale is a watershed zone supplied by the distal intraparenchymal penetrating arterioles[7,8] and is the most distal white matter area perfused by collateral vessel circulation through the anterior portion of the circle of Willis after ICO. Hypoperfusion from ICO generates ischemic changes in this area at an early stage. We reported that the confluent high-intensity area on T_2-weighted images in the middle centrum semiovale contained increased CBV.[17] This finding indicates that this high-intensity area that is susceptible to a reduction in perfusion pressure has prominent compensatory vasodilatation.[18] We also showed in this study that patients with this high-intensity area had less hemodynamic reserve, decreased CBF, increased OEF, and decreased CBF/CBV ratio in the cerebral cortex compared with those without it. Minor cerebral perfusion pressure change would elicit more devastating CBF reduction, resulting in ischemic changes in such less reserved hemisphere than normally perfused brain.[18,19] This high-intensity area on MRI is a serious sign of a deterioration of hemodynamic state in ICO with good collateral vessel circulation through the anterior portion of the circle of Willis.

Few studies have attempted to correlate white matter lesions on MRI with CBF and metabolism.[20-24] In carotid artery diseases with various degrees of white matter lesions, only multiple large or confluent white matter lesions in any location are accompanied by reduced cortical CBF, with no relationship between the degree of the white matter lesions and the severity of the hypoperfusion.[22] White matter lesions, without taking into account their topography, are nonspecific findings and do not relate to the hemodynamic change resulting from carotid artery disease. We should note whether high-intensity areas exist in the region vulnerable or not vulnerable to decreased perfusion.

CONCLUSION

The confluent high-intensity area on T_2-weighted images in the middle centrum semiovale indicates hemodynamic compromise in ICO with good collateral vessel circulation through the anterior portion of the circle of Willis. Detection of this abnormality necessitates strict control of systemic hemodynamic factors, such as systemic blood pressure and blood viscosity,[25,26] and further investigation of the hemodynamic state of general circulation. Ischemic changes resulting from hypoperfusion may, in their early stages, produce only subtle, subjective symptoms but be easily detectable with MRI. Therefore, MRI is a useful diagnostic tool to identify patients at risk for hemodynamic ischemia before the development of major neurologic deficits or infarction.

We thank to Yoshihara Yonekura, MD, and Yasushi Iwasaki, MD for their support and advice.

Automatic Memory Processes in Patients With Multiple Sclerosis

Jordan Grafman, PhD; Stephen Rao, PhD; Linda Bernardin, MS; Gary J. Leo, DO

• To better understand the nature of the memory deficit in patients with multiple sclerosis, we designed a study to compare automatic vs effortful memory processes. Forty-one patients with definite multiple sclerosis and 45 demographically matched normal control subjects were administered two tasks designed to assess both automatic (monitoring frequency and modality) and effortful (free and cued-recall) processing. Results indicated that patients with multiple sclerosis, as expected, were significantly impaired on memory measures requiring effort, but performed normally on automatic measures. Performance on the memory indexes did not correlate with self-reported depression. The implications of these findings for delineating the locus of the memory impairment in multiple sclerosis is discussed.

(*Arch Neurol.* 1991;48:1072-1075)

Recent neuropsychologic studies have shown that approximately 50% of patients with multiple sclerosis (MS) exhibit disorders of memory (for a recent review of this literature, see Grafman et al[1]). The most common form of memory loss is characterized by an impairment in episodic memory, defined as an inability to retrieve daily events that occur at a specific time and place.[2-7] Only rarely do MS patients experience difficulty with semantic memory, ie, retrieving names, facts, and concepts.[8,9] This distinction between episodic and semantic memory is a popular one, which has been intensively studied in normal and impaired populations.[10-12]

Another useful distinction in characterizing memory processes contrasts effortful vs automatic cognitive operations.[13,14] *Effortful* operations usually refer to explicit search and strategy procedures used to encode and then recall or recognize previously presented material. *Automatic* operations, in contrast, tend to require less focused attention and are involved in encoding and retrieving the (task-defined) less salient aspects of a stimulus.[15-17] Hasher and Zacks[13] described a variety of tasks that fulfilled their criterion for measuring automaticity and included tests of frequency (eg, how often a stimulus appeared[18]) and stimulus modality (eg, recall of whether an item was originally shown as a picture or word) monitoring. Automatic operations appeared to demand less sustained concentration and fewer cognitive resources.[16,17] Thus, items automatically processed should be equally recalled under intentional and incidental encoding conditions. Furthermore, practice in coding frequency or modality would also be expected to have little effect on effortful recall of item frequency or modality.[19] In addition, attention to other aspects of a task should not detract from automatic processing.[14]

One test of the functional independence of automatic memory operations would be to study abnormal populations on tasks requiring both automatic and effortful operations.[20,21] Because an aspect of the way in which people remember events in episodic memory (eg, events occurring while eating dinner at a new restaurant) is by "automatically" recording the less salient or attended-to properties of episodes (eg, how long it took to eat dessert) in parallel with "effortful" processing during the episode (eg, remembering where one ate for dinner), it might be expected that both processes would be adversely affected by central nervous system diseases such as MS that affect retrieval of episodic memories. In addition, because automatic processing should be resistant to changes in effort or motivation,[22] it might be a particularly sensitive measure (compared with other standard effortful memory measures such as story recall or word list learning) to use in separating out the effects of depression from the more direct effects of MS on memory. The effort required to encode information using cognitive strategies may be constrained by certain symptoms found in depressed patients, such as lack of energy or amotivation.

In the experiments reported below, we utilized two tasks designed to evaluate automatic and effortful processing. One task evaluated subject sensitivity to the frequency of stimulus presentation using both frequency monitoring and free-recall measures, while the other task evaluated paired-associate learning using both stimulus modality monitoring and free and cued-recall measures. We predicted that MS patients would not be impaired on automatic processing measures, but that their performance on the effortful measures would distinguish them from control subjects.

SUBJECTS AND METHODS

Subjects

Patients with MS (n = 41) and matched control subjects (n = 45) were included in this study. The MS patients who participated in this study were recruited randomly from a membership listing compiled by a local MS society. Medical records were reviewed to determine the basis for the diagnosis of MS. In addition, all patients underwent a neurologic examination and magnetic resonance imaging as part of the present study. Diagnosis was established by the results of neurologic and neuro-ophthalmologic examination, evoked potentials, cerebrospinal fluid analysis, and brain imaging. As a result of the recruitment method, all but two (4.9%) patients were in remission at the time of the evaluation. All patients met the criteria for clinically or laboratory-supported definite MS, as determined by the criteria of Poser et al.[23] Patients with a history of alcohol or drug abuse or nervous system disorders other than MS were excluded. Physical disability was rated on the 10-point Expanded Disability Status Scale.[24] Eight (19.5%) patients were taking potentially psychoactive medications at the time of the evaluation. No MS patient rated as clinically depressed on the Zung Depression Scale (see below) had received electroconvulsive therapy.

Control subjects were also screened for evidence of cognitive dysfunction, neurologic disorders, alcohol or drug abuse, or positive psychiatric history and were excluded if they had a first-degree relative with either major affective disorder or dementia. Subjects were matched as closely as possible for sex, age, and education level (Table). Both MS patients and control subjects were paid for their participation in this study.

Both groups were administered the Mini-Mental State[25] dementia examination, and the Zung Self-Rating Depression Scale.[26] The MS group reported significantly more

symptoms of depression than did control subjects (Table). In addition, there was a marginally significant group difference on the Mini-Mental State examination.

Testing

Control subjects and MS patients were administered all tests during the same testing session at the Medical College of Wisconsin, Milwaukee. Test administration was counterbalanced within groups.

Frequency Monitoring.—We used a version of the Hasher and Zacks[14] Frequency Monitoring Task. A list of 90 words was read to the subjects at a rate of one word every 3 seconds. Within the list, some words were presented once, others twice, three times, and up to seven times. Subjects were asked to listen carefully and try to remember the words. After a brief interval at the end of the testing session, subjects were asked to recall all the words that they could remember from the list (free recall). Following another brief delay, subjects were told that they would be presented with a set of words from the list (they were also told that some of the words had not been presented) and were asked to judge how often the word had appeared on the previous list (frequency monitoring). Scoring included total number of words recalled in the free-recall condition, number of words freely recalled from each frequency category, and a subject estimate of the number of times words from each frequency category appeared on the original list. In addition, we subtracted the estimated mean frequency of words that actually appeared from one to three times on the list from words that appeared four to seven times to obtain an index of frequency monitoring. The numbers of words for each actual frequency (AF) category were presented to subjects in the estimation part of the task as follows: AF0 = 3; AF1 = 4; AF2 = 5; AF3 = 6; AF4 = 6; AF5 = 3; AF6 = 2; and AF7 = 1.

Paired-Associate Learning Test.—Subjects were shown 32 pairs of stimuli. Eight of the pairs were concrete, imaginable words, eight of the pairs were pictures (line drawings of objects), eight pairs were composed of a word-picture combination, and the last eight pairs were of the picture-word form. Half the pairs were made up of related items; half were unrelated. After viewing all the pairs, subjects were asked to freely recall all of the items that were presented. Next, subjects were shown a cue (the initial item of a pair) and asked to recall the associate. Finally, subjects were told that they would hear the names of all items that were on the test and would be asked to say whether they were originally presented as a picture or as a word. Variables of interest include free and cued recall and modality of presentation. Remembering whether an item was presented as a word or as a picture was considered an incidental learning (ie, automatic processing) condition. One MS patient did not take this test.

The key variables of interest were the effects due to group and those due to type of cognitive processing operation (ie, effortful vs automatic). *Effortful operations* in both the Paired-Associate and Hasher Frequency Estimation tasks were considered the free and cued-recall measures. *Automatic operations* were represented by the frequency estimation and modality monitoring measures. A more complete description of the tasks used here and their relationship to each other can be found in a study by Weingartner et al.[27] Statistical comparisons used analysis of variance for main effects and Tukey-B tests for group comparisons. Correlations were completed using Pearson product correlation coefficients. All data are reported as means ± SDs.

Subject Table

	Patients With Multiple Sclerosis (n = 41)	Normal Control Subjects (n = 45)
Age, y	47.8 (7.9)	47.0 (8.3)

RESULTS

Effortful Processing: Free and Cued Recall

We first compared overall free recall on the Hasher Frequency Monitoring Task and found a significant between-group difference ($F[1,84]=7.41$; $P<.008$). In addition, we found an expected significant main effect for frequency ($F[3,252]=59.48$; $P<.0001$) but a nonsignificant group × frequency interaction ($P>.10$). Control subjects recalled significantly more words than did MS patients, but both groups benefited in free recall by having words repeated during stimulus presentation (Fig 1). Results from the free-recall portion of the Paired-Associate Test (Fig 2) again revealed that control subjects recalled more items than did MS patients ($t[83]=-4.20$; $P<.0001$). Under cued-recall conditions (Figs 3 and 4), there was a significant between-group effect for the related *and* unrelated pairs comparison ($F[1,83]=9.64$; $P<.003$) as well as for all the picture-word pair combinations ($F[1,83]=9.64$; $P<.003$). Both control subjects and MS patients remembered more related than unrelated pairs ($F[1,83]=591.37$; $P<.0001$) and more pairs when the item cue was a picture ($F[3,249]=16.75$; $P<.0001$). None of the group by condition interactions were significant for cued-recall processing.

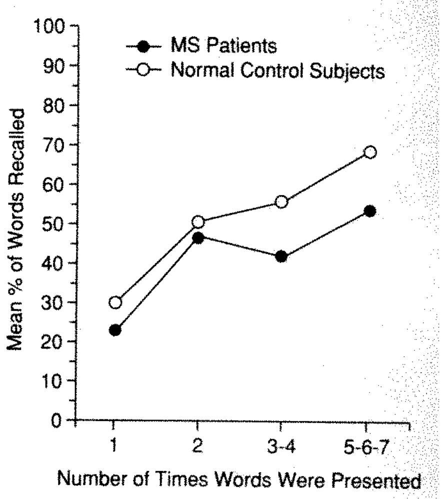

Fig 1.—Hasher Frequency Discrimination Task: free recall of words as a function of how frequently a word had been presented. MS indicates multiple sclerosis.

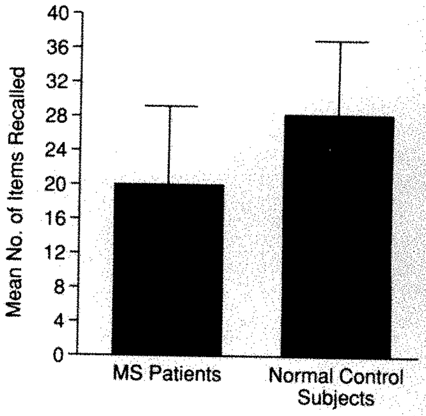

Fig 2.—Paired-Associate Test: free recall. MS indicates multiple sclerosis.

Automatic Processing: Frequency and Modality Monitoring

When asked to estimate the frequency with which a word appeared on the Hasher Frequency Monitoring Task word list (Fig 5), both control subjects and MS patients demonstrated that they were sensitive to increasing frequency of stimulus presentation ($F[7,588]=154.93$; $P<.0001$). There were no overall between-group differences in frequency estimation ($P>.10$), although a significant group by frequency interaction effect ($F[7,588]=4.50$; $P<.001$) was found, indicating that MS patients tend to make judgments that underestimate frequently presented words and overestimate words that were presented infrequently or even not at all. As far as modality monitoring on the Paired-Associate Test was concerned (Fig 6), there were no significant between-group differences.

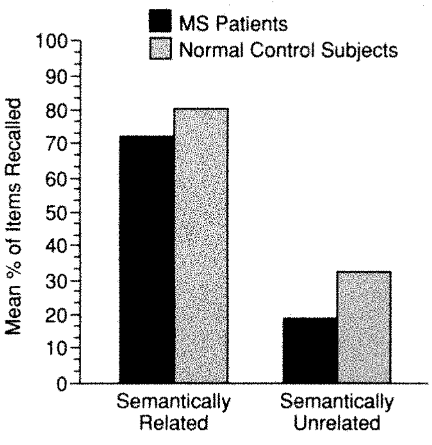

Fig 3.—Paired-Associate Test: cued recall as a function of semantic relatedness. MS indicates multiple sclerosis.

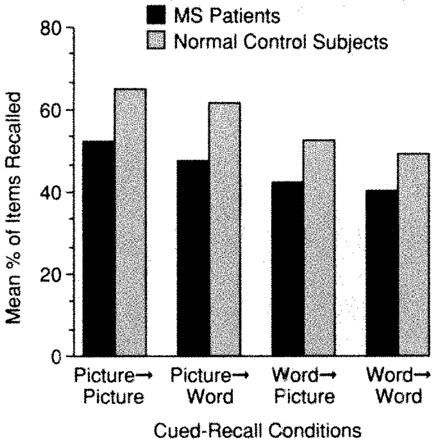

Fig 4.—Paired-Associate Test: cued recall as a function of stimulus modality pairing. MS indicates multiple sclerosis.

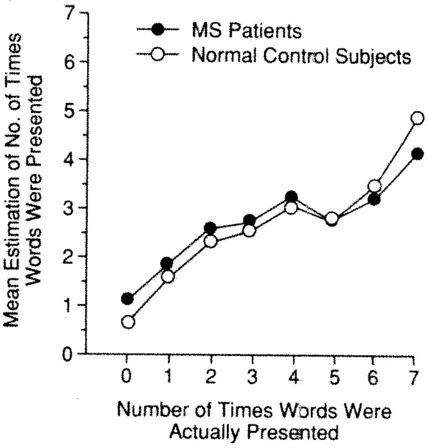

Fig 5.—Hasher Frequency Discrimination Task: estimations of the number of times a word had been presented on the study list (automatic processing). MS indicates multiple sclerosis.

Other Results

There were no group differences on the number of intrusions for either test. For the MS patients, the free-recall measures from both tests were significantly correlated ($r=.58$, $P<.0001$), as were the two automatic memory measures (frequency/modality monitoring; $r=.45$, $P<.005$). In contrast, for the control subjects, the free-recall measures were significantly correlated ($r=.63$, $P<.0001$), but the frequency/modality measures were not ($r=.26$, $P>.05$). This might be due to a ceiling effect for the control subjects on the modality monitoring measure.

There were no significant ($P<.01$) correlations between the automatic and effortful memory measures and depression (Zung scale), physical disability (Expanded Disability Status Scale), duration of symptoms, or education.

COMMENT

Our results indicate that MS patients, like control subjects, are sensitive to the less attended aspects of stimulus processing such that they are able to retrieve incidental properties (ie, the modality of a stimulus or its frequency of presentation) of a stimulus that elicited predominantly semantic processing. On the frequency monitoring measure, MS patients tended to underestimate frequently presented items and overestimate rarely presented items, suggesting that they adapted a conservative scaling bias. As expected, the MS patients had some difficulty on effort-demanding memory measures such as free and cued-recall processings. However, their performance on cued-recall processing was as sensitive as that of the control subjects to the conditions of relatedness and type of cue. This finding of effortful memory deficit is rather nonspecific because it occurs in almost all patients with brain disease or serious psychiatric disorder and it has been observed across almost all studies of MS. Our results also indicated that level of depression played no role in the effortful memory deficit of patients with MS.

Why do MS patients succeed on these measures of automatic processing despite problems in effortful processing? Hirst and Volpe[17] described the performance of amnesics on measures of automatic processing and reported that adequate performance on such measures required relatively intact *effortful* processing. Yet Beatty et al[28] and Rao et al[29] have found that MS patients who also have poor effortful memory as seen on free and cued-recall tasks do well on automatic and implicit memory tasks. Perhaps so-called automatic operations basically represent another form of implicit priming, which appears relatively intact in MS patients. In this case, one possible explanation for the good performance of MS patients on automatic processing measures despite impaired effortful memory is that their memory deficit may primarily involve the conscious, effortful *strategic* aspects of searching long-term memory. Because automatic and incidental memory processes by their very definition should be independent of conscious, effortful strategic *search*, but still require intact memory encoding and *storage*, they could be spared in MS patients. This would suggest that the efficiency of "automatic processes" may also depend on having adequate resources to process information in parallel. Depending on task instructions, some aspects of information (eg, meaningfulness) are processed using focused attention; other aspects of information (eg, phonological information) may be processed outside the window of focused attention. This passive parallel processing of information also has to time-share resources with concurrent active processing such as overt verbal rehearsal. What we are calling the passive processing of information is similar to even more covert activation processes such as those used in implicit memory tasks. Thus, adequate automatic processing should depend more on the passive strengthening of previous semantic representations and their associational links, relative to the effort made in strategic or controlled memory search.

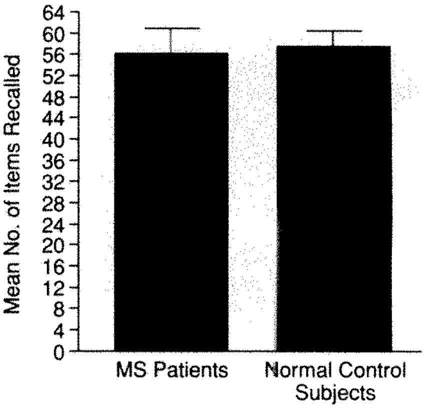

Fig 6.—Paired-Associate Test: incidental recall of whether a test item was originally presented as a picture or word (automatic processing). MS indicates multiple sclerosis.

Therefore, it follows that if certain representations and their associational links are spared in selected central nervous system disorders like MS, then their "slavish" specific automatic processes may be spared too. This hypothesis would be better tested in patients with unilateral cortical lesions rather than MS. For example, an effortful measure such as remembering words might be impaired in left-hemisphere patients, but incidentally identifying the location where words were presented in a grid (a candidate for an automatic measure in this scenerio) might be spared (if "right-hemisphere spatial location processes" remained intact).

An alternative explanation for intact automatic processing in light of impaired effortful processing in MS patients is that they may have difficulty coding verbal information within working memory.[4] In particular, there is some evidence that MS patients have problems in temporarily storing phonological information within a rehearsal loop for later processing. In this model, automatic processing requires intact semantic activation processes that can operate independently of working memory (and that appear intact in MS), whereas effortful structurally based processes (eg, covert rehearsal of verbal-phonological information) depend on activating buffers within working memory (that appears affected by MS).

Processes such as frequency and modality estimation will rarely meet all the strict criteria for automaticity established by Hasher and Zacks.[13,14] Some researchers have described these so-called automatic processes as requiring *relatively* less focused attention than effortful structural or semantic categorization/identification but lying on a *continuum* of attention and effort during encoding.[30,31] Thus, by manipulating encoding strategy and attentional effort, accuracy in estimating frequency or the modality of a stimulus can be degraded.[32,33] Neither of those manipulations were done in the present study.

As noted above, the evidence from the performance of the MS patients whom we studied suggests that simply a decrease in effortful processing (reflected in *particularly* impaired free recall) will not correspond to impaired accuracy in modality or frequency estimation. However, even in the case of patients with dementia of the Alzheimer's type who demonstrate impaired frequency and modality estimation along with impaired effortful processing, there was no significant rank-order correlation between free recall and accuracy in frequency or modality estimation.[20]

Thus, our findings would argue for at least a partial independence of the cognitive processes required for frequency and modality monitoring from those required for effortful encoding and retrieval. Automatic processes bear some resemblance to implicit memory processes that may depend on intact cortical structures, whereas effortful or explicit memory processes may depend more on subcortical structures such as the hippocampus. Since plaques in MS tend to appear in subcortical regions, it should be expected that effortful memory processes are most at risk in MS.

Other studies[28,29] have demonstrated that MS patients perform better on tasks not requiring declarative memory such as procedural learning and priming and have access to semantic knowledge. In addition, MS patients tend to perform much better on recognition vs recall measures.[34] Measures of automatic processing can now be added to the list of measures on which MS patients perform normally. Nevertheless, most measures requiring free or cued-recall processing appear disturbed to various degrees in MS patients. In the future, we plan to conduct follow-up studies of MS patients employing conditions such as rate of information presentation, phonological and information load, interference, and type of retrieval required to better identify the locus of the memory deficit.

This study was supported in part by providing facilities (to Dr Grafman) and by awarding a research career development grant (K04 NS 01055-05) and research grant (R01 NS 22128-06) (both to Dr Rao) by the National Institute of Neurological Disorders and Stroke.

Importance of Intrathecal Synthesis of IgD in Multiple Sclerosis

A Combined Clinical, Immunologic, and Magnetic Resonance Imaging Study

Mohammad K. Sharief, MB, ChB, MPhil, Romain Hentges, MD

• There is increasing evidence that soluble IgD has a certain role in the humoral immune response within the central nervous system. We report herein the results of a combined clinical, magnetic resonance imaging, and immunopathologic study to determine the clinical importance of intrathecal IgD synthesis. Intrathecal synthesis of IgD (detected through the calculation of index values) was studied in 64 patients with multiple sclerosis and in 50 neurologic control patients and normal subjects. Locally secreted IgD was detected in 30% of patients with clinically active multiple sclerosis, including two in whom magnetic resonance images of brain and spinal cord were normal and who had no evidence of intrathecal IgG synthesis. No intrathecal IgD production was detected in patients with clinically stable multiple sclerosis or those suffering from chronic progressive multiple sclerosis, while it significantly correlated with the interval from the last relapse and with the total duration of the disease process in patients with relapsing, remitting multiple sclerosis. Intrathecal IgD synthesis also correlated with the degree of cerebrospinal fluid pleocytosis and with the presence of free κ and λ light chain bands in cerebrospinal fluid. Present results supplement and expand earlier data and suggest that intrathecally secreted IgD is a putatively important part of the immune response in clinically active relapsing, remitting multiple sclerosis.

(*Arch Neurol.* 1991;48:1076-1079)

IgD is expressed on greater than 90% of mature B lymphocytes[1] and is considered to be an indicator of B-cell maturity. Evidence suggests that soluble (ie, secreted) IgD has a legitimate antibody function[2] that makes it particularly helpful in the study of early immune response, including that of the central nervous system.[3] The level of soluble IgD in cerebrospinal fluid (CSF), however, is extremely low compared with levels of IgG, IgA, and IgM and is technically difficult to detect. Thus, although IgD levels in the normal reference population[4] and in various neurologic disorders[5] have been previously described, intrathecal production of IgD, through the calculation of the IgD index, has only recently been reported.[6,7]

So far, the clinical importance of intrathecal IgD synthesis in patients with multiple sclerosis (MS) has not been evaluated. Similarly, immunopathologic correlation of this finding with other CSF features of MS has not been properly investigated. We report herein a combined study in which we evaluated the relationship of intrathecal production of IgD to both clinical and paraclinical manifestations of MS.

PATIENTS AND METHODS

Patients

Paired CSF and serum samples from 64 patients with clinically definite MS[8] were utilized in our study (Table 1). Patients with clinically active disease had not received immunomodulatory treatment within 9 months of CSF collection. Patients with chronic progressive MS had progressed steadily since the onset of their disease,[9] while patients with clinically stable MS had relapsing, remitting disease and were in clinical remission at the time of the lumbar puncture.

The neurologic control group (Table 1) contained patients with various neurologic disorders in whom immunologic mechanisms were unlikely to participate. This control group included patients with Alzheimer's disease (four patients), benign intracranial hypertension (four patients), cervical spondylosis without myelopathy (three patients), epilepsy (three patients), amyotrophic lateral sclerosis (five patients), cerebrovascular diseases (four patients), Parkinson's disease (four patients), and peripheral neuropathy (five patients). Normal control subjects presented with tension headache or neurosis and detailed clinical and laboratory investigations showed no sign of neurologic disease. These normal subjects were included to calculate normal reference ranges of IgD and IgG in CSF and serum samples.

Preparation of Samples

Paired CSF and serum samples were collected simultaneously, and 1000 kallikrein inactivator units of affinity purified protease inhibitor, aprotinin (A4529, Sigma Chemical Company, St Louis, Mo), were immediately added to each millimeter of test samples to prevent IgD degradation. Cerebrospinal fluid samples were selected to exclude xanthochromic specimens and specimens containing more than one erythrocyte per field at the time of collection. The CSF samples were centrifuged for 20 minutes at 200*g*, and then both CSF and serum specimens were frozen in aliquots at −70°C immediately after centrifugation and thawed just before use.

Quantitative Determinations

IgD concentration in CSF and serum samples was determined by enzyme-linked immunosorbent assay, as recently described.[7] In brief, wells of polyvinyl chloride microtiter plates were coated with 100 mL of 1:4000 dilution of anti-human δ chain antiserum (A-093, Dakopatts, Dako, Copenhagen, Denmark), blocked by 2% bovine serum albumin and 0.1% polysorbate (Tween, BDH Ltd, Poole, England) in phosphate-buffered saline, then incubated with test samples. After overnight incubation, IgD reactivity in the test samples was detected by affinity

Table 1.—Clinical Features of the Study Population

Clinical Group	Total No. (Female)	Mean ± SD Age, y	Mean ± SD Disease Duration, y
Clinically active multiple sclerosis			
Relapsing remitting	34 (20)	33.2 ± 5.7	7.9 ± 4.2
Chronic progressive	14 (9)	37.1 ± 7.6	9.4 ± 5.1
Clinically stable multiple sclerosis	16 (10)	35.6 ± 6.4	7.1 ± 5.6
Neurologic controls	32 (17)	40.2 ± 11.3	. . .
Normal subjects	18 (10)	31.5 ± 8.2	None
Total	**114 (66)**	35.5 ± 7.8	. . .

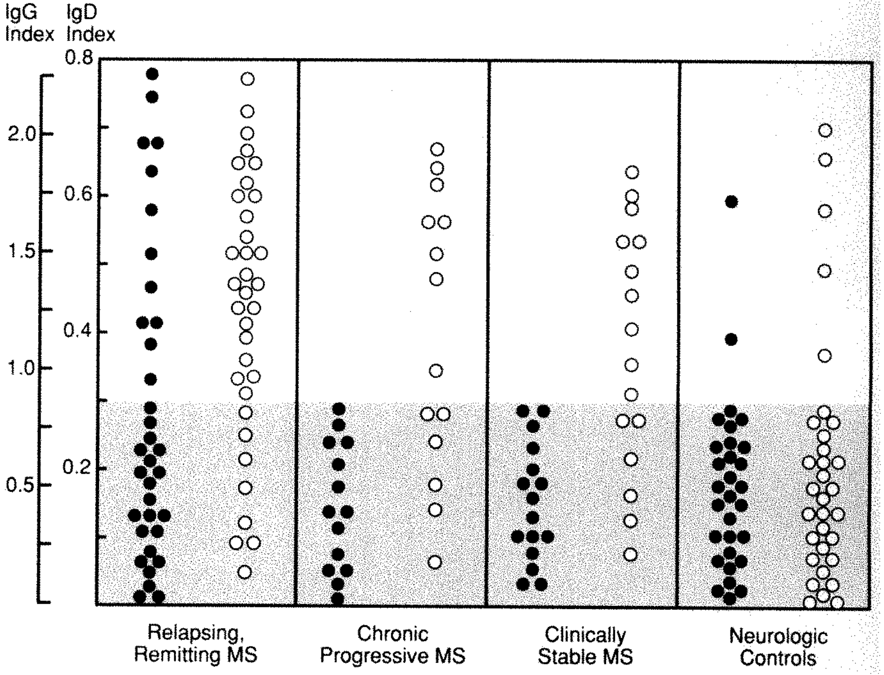

Fig 1.—Individual levels of IgD (closed circles) and IgG (open circles) indexes in the various study groups of patients with multiple sclerosis (MS). Shaded area represents the cutoff value of both indexes in the normal reference population. Statistical analyses are presented in the text.

purified rabbit peroxidase-conjugated antihuman δ chain (A-6281, Sigma). Known amounts of human IgD standard (OTRD 03, Behring, Marburg, Germany), as well as control CSF and serum, and background control wells were included in each plate. Optical densities of test samples were averaged, read from the standard curve, and corrected by the original dilution factor. Albumin and IgG concentrations in CSF and serum specimens were assayed by electroimmunoassay.[10] Total protein content in CSF was measured turbidometrically with the benzethonium chloride precipitation technique.[11]

Other CSF Tests

The CSF specimens were examined for pleocytosis within 6 hours of the lumbar puncture. Cell count was performed with the use of Fuchs-Rosenthal chambers (Hemocytometer, Aimer Products, London, England), and cytologic examination was performed with a Giemsa stain from a cytocentrifuge (Cytospin 2, Shandon Products Ltd, Cheshire, England) preparation. Oligoclonal κ and λ light chain bands in the CSF were detected by replicate immunoblotting technique.[12]

Evaluation of Intrathecal Immunoglobulin Synthesis

Intrathecal production of immunoglobulins was determined by calculating the immunoglobulin index value,[13] which compensates for the influence of leakage of immunoglobulin from the plasma into CSF. The immunoglobulin index was determined according to the following formula: CSF immunoglobulin × serum albumin/serum immunoglobulin × CSF albumin.

Magnetic Resonance Imaging (MRI)

All patients with clinically active MS underwent MRI as part of their routine investigations, and the images were reviewed by experienced radiologists who were "blinded" to the CSF data. Magnetic resonance imaging was performed on a 0.27-T superconducting imager (Picker International, Cleveland, Ohio). The same spin-echo sequence ($SE_{2000/60}$ [numbers are milliseconds]) was performed in all patients who underwent MRI.

Statistical Methods

Values were evaluated, as appropriate, by Spearman's Rank Correlation Coefficient, linear correlation coefficient, Student's t test, and the Wilcoxon Rank-Sum Test. Statistical analyses were performed with SPSS/PC$^+$ software (SPSS Inc, Chicago, Ill).

RESULTS

CSF IgD Estimation

The IgD enzyme-linked immunosorbent assay showed a coefficient of variation of 5.1% within and 5.8% between batches and had a detection limit of 0.2 ng/L. Separate studies on samples without aprotinin showed that addition of the protease inhibitor has improved detectability of CSF and serum IgD by a factor of 5. Detectability of IgG, however, was not altered by the addition of aprotinin.

One normal control subject was a high outlier for CSF IgD concentration, and the IgD amount was undetectable in three of the 18 normal control subjects and in two patients of the 32 subjects in the neurologic control group (one with Alzheimer's disease and another with epilepsy). These patients were excluded from the calculations of CSF IgD results.

In the reference control group, the CSF IgD showed a log normal distribution. Logarithmic transformation resulted in a mean ± SD reference CSF IgD of 1.86 ± 0.62 mg/L (range, 0.7 to 459 mg/L) and serum IgD of 1.54 ± 0.78 mg/L (range, 0.1 to 128 mg/L). The IgD index in the reference group was 0.12 ± 0.085, while the mean IgG index was 0.53 ± 0.16.

IgD Index in MS

High levels of IgD index were detected in the CSF of 12 patients (30%) with clinically active MS but was not detected in any patient with stable MS ($P<.01$; Fig 1). None of the patients with chronic progressive MS demonstrated a high IgD index value. Significantly higher IgD index values were seen in patients with active relapsing, remitting MS compared with the neurologic control group ($P<.02$). Only two neurologic control patients (6%) showed an abnormally high IgD index; one was suffering from type 1 hereditary sensory and motor neuropathy, while the other sustained a pontine infarct. Both also demonstrated high IgG index levels.

In patients with relapsing, remitting

MS, high IgD index levels correlated with the interval that separates the onset of a clinical relapse and the lumbar puncture. Of 21 patients who had the lumbar puncture within 1 week of a relapse, 11 (52%) demonstrated high IgD index values, while only one of 13 patients from whom CSF was collected more than a week (mean, 3.6 weeks) after the onset of relapse had a high IgD index ($P<.01$). High IgD index values, however, did not significantly correlate with the number of relapses in patients with relapsing, remitting disease. A negative correlation was found between IgD index and the total disease duration in patients with active MS (Fig 2).

IgD Index and CSF Features in MS

The relationship between IgD and IgG indexes in different groups of patients with MS has already been shown in Fig 1. Abnormally high IgD index levels were detected in two patients with active MS who had a normal IgG index. IgD index values in patients with MS failed to correlate with IgG index values ($r=.426$, $P=.08$). Furthermore, high IgG index values were detected in both clinically active and stable MS groups. Five patients (16%) in the neurologic control group had abnormally high IgG index levels: two presented with stroke, one with cervical spondylosis, and two with a high IgD index (see above).

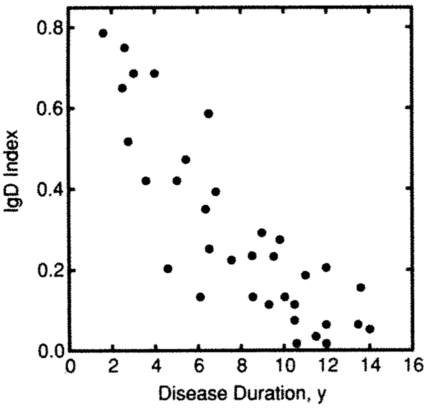

Fig 2.—Correlation of IgD index to total disease duration in patients with clinically active relapsing, remitting multiple sclerosis ($r=.857$, $P<.001$).

IgD index significantly correlated with CSF pleocytosis ($P<.005$) and with the detection of CSF reactive lymphocytes, ie, cells with altered staining characteristics due to increased cytoplasmic contents of immunoglobulins ($P<.01$; Table 2). A significant correlation was also found between high IgD index and the presence of free κ ($P<.005$) and free λ ($P<.001$) light chain bands in the CSF (Table 2). There was no significant correlation between IgD index and CSF-bound κ or λ light chain bands. Similarly, there was no correlation with CSF total protein content.

IgD Index and MRI Findings in MS

Table 3 summarizes data obtained from a comparison of MRI findings with IgD index values. High IgD index levels were detected in two patients with MS who had normal MRI scans. These two patients also had normal IgG index levels. No significant correlation was found between IgD index and either the total number of MRI lesions or their anatomic distribution.

COMMENT

Human IgD is different from other immunoglobulins in structure, exon arrangement, and physiologic location (reviewed by Blattner and Tucker[14]). The secreted form is a monomer, with a sedimentation rate of 7 *s*, which consists of two heavy (κ) and two light chains. Unlike other immunoglobulins, IgD has a relatively large hinge region that is sometimes present between the first and second region domains, probably to introduce flexibility into the structure to allow the antigen binding site to achieve better contact with antigens.[15] The suggestion that IgD has no function or that it simply serves as an auxiliary antigen receptor on B cells[16] seems a trivial interpretation of the evolution of such a complex system.[14] Despite its discovery two decades ago,[17] the biologic function(s) of soluble IgD is not fully understood because of its very low serum concentration. The levels of soluble IgD in human CSF are even lower, so when relatively insensitive methods of detection are utilized, none could be detected.[18,19] Furthermore, secreted IgD is susceptible to rapid proteolysis, probably by plasmine, although the addition of ε-aminocaproic acid, which is a relatively specific inhibitor of plasmine activation, failed to stop spontaneous protein degradation in some cases.[20] We found that the addition of enzyme inhibitor of a wider spectrum, eg, aprotinin, prevents protein fragmentation in all patients studied so far.

Results obtained in our reference group showed CSF and plasma levels of IgD and IgD index values relatively similar to those previously reported.[6,7] The data reported herein extend these reports and provide good evidence that intrathecal synthesis of IgD could be detected in a substantial number of patients with clinically active MS. The significant correlation of intrathecally synthesized IgD with clinical and

paraclinical variables in MS suggests that secreted IgD is not merely the result of cell surface shedding, as previously suggested.[21] Although systematic studies are warranted to establish the IgD profile in relation to clinical variables in greater detail, the detection of high IgD index values might have a place in routine characterization of the humoral immune response in patients with MS. Moreover, the demonstration that high IgD index values are predominantly detected in MS relapse may imply that they could be regarded as a reasonable indicator of relatively active disease. In contrast, no significant difference in intrathecal IgG synthesis was detected between clinically active and stable disease processes.

The absence of intrathecal synthesis of IgD in patients with chronic progressive MS is interesting. There have been several reports suggesting basic differences between chronic progressive and relapsing, remitting MS, which were based on genetic[22] and epidemiologic[23] studies. Furthermore, fundamental differences in clinical[23,24] and neuroimaging[25] features were noticed between the two MS groups. The data described in our study show a basic difference in the intrathecal IgD pattern between the two groups of patients with MS. In contrast, previous studies of CSF IgG, IgM, and IgA changes failed to detect any change in immunoglobulin pattern. Lolli and collaborators,[7] however, reported lower plasma IgD levels in patients with chronic progressive MS compared with those with relapsing, remitting disease.

The absence of a significant correlation between intrathecal IgD synthesis and MRI-detected lesion burden is not surprising. Muller and collaborators[26] failed to establish any correlation between CSF absolute γ-globulin production and quantified MRI changes in patients with MS. It is quite difficult to test for the relative number of new plaques in routine MRI, as chronic lesions are also visible.[27] Until the correlation between the measured factors in acute states is standardized, one should not draw conclusions as to the precise relationship among new plaques, intrathecal IgD synthesis, and the number of MRI-detected high signals.

The intrathecal production of IgD in 30% of patients with MS and the fact that this IgD production is mainly detected in patients with recent relapse indicates that IgD may play a role in the regulation of intrathecal humoral immune response in patients with MS.

We wish to thank Naghat Lakdawala, MSc, for her help in the preparation of the samples and June Smalley for her excellent technical help in the preparation of the manuscript. Critical discussions with laboratory technicians were greatly appreciated. Magnetic resonance images were obtained in Queen Square, London, and Belgium Imaging Centres, Brussels.

Serologic Evidence of *Campylobacter jejuni/coli* Enteritis in Patients with Guillain-Barré Syndrome

Ruben Gruenewald, PhD; Allan H. Ropper, MD; Hermy Lior, MSc;
Joseph Chan; Richard Lee; Vernaleah S. Molinaro

• We performed serologic testing for *Campylobacter jejuni* in 17 consecutive patients with acute Guillain-Barré syndrome from the Boston, Mass area to compare the frequency of this preceding infection with the high rates reported from other areas of the world. The rate of seropositivity, 18%, was considerable, but it was lower than that reported in Australia. Moreover, all of our patients with definite serologic evidence of infection had severe enteritis before Guillain-Barré syndrome, usually with the organism cultured from stool samples. *Campylobacter* enteritis is an important antecedent illness for Guillain-Barré syndrome but did not precipitate the disease without enteritis.

(*Arch Neurol.* 1991;48:1080-1082)

Acute infectious illnesses occur 1 to 3 weeks before Guillain-Barré syndrome (GBS) in approximately two thirds of patients, but specific pathogens are infrequently identified.[1,2] Infection with *Campylobacter jejuni/coli* has been highlighted as preceding GBS by a number of groups who have isolated the organism from the stool of patients with GBS or demonstrated *C jejuni/coli*–specific antibodies in serum or spinal fluid.[1-8] With the use of an enzyme-linked immunosorbent assay, Kaldor and Speed[2] found that 21 (38%) of 56 Australian patients with GBS had serologic evidence of *C jejuni* infection, and with the use of an immunodot assay, Speed et al[7] found *C jejuni/coli*–specific antibodies in 22 (49%) of 45 patients with GBS. These studies, if true in other geographic areas, would make *C jejuni* the most common pathogen that precedes GBS, exceeding the combined incidence of Epstein-Barr virus, cytomegalovirus, and *Mycoplasma* infections. *Campylobacter jejuni* is also interesting because it is one of the few bacteria that has been associated with GBS, and serologic evidence of infection in patients with GBS has been found in the absence of gastrointestinal symptoms.[2]

We therefore studied the frequency of *C jejuni/coli*–specific IgG, IgM, and IgA antibodies in 24 plasma and serum samples from 17 consecutive patients with GBS from the Boston, Mass area. Our results were similar to findings in a study from the United Kingdom,[8] but lower than the rates suggested by Australian studies. Moreover, all of our patients with definite serologic evidence of infection had severe enteritis.

PATIENTS AND METHODS

Patients

Seventeen consecutive patients who were admitted to the Massachusetts General Hospital, Boston, between January 1988 and January 1989, and who fulfilled the criteria for GBS according to the National Institute for Neurological and Communicative Disorders and Stroke, were studied (Table). All of the patients had typical acute GBS, although one subsequently had a course that was more consistent with relapsing inflammatory demyelinating neuropathy (Table, patient 5), one had severe GBS and prominent dysautonomia (Table, patient 16), and one later became ill with Hodgkin's disease (Table, patient 11).

Prodromal Illness

Six patients had preceding gastrointestinal illnesses, and six patients had respiratory prodromal illnesses, 1 to 47 days before neurologic symptoms, whereas five patients reported no illness (Table). Three of the patients with gastrointestinal prodromes had abdominal cramping, diarrhea (bloody in two patients), and fever that were compatible with bacterial enteritis. One patient was hospitalized for these symptoms and had no enteric pathogens cultured from a stool sample that was taken 47 days after the illness (Table, patient 7). Two other patients had *C jejuni* cultured from stool samples during the acute illness. Three patients had nausea, vomiting, or minimal nonbloody diarrhea. One of these patients had stool cultures, but no enteric pathogens were recovered. Of the six patients with respiratory illnesses, one had pneumonia with dry coughing and chills, as well as elevated titers of cold agglutinins, and another patient had fever, chills, and muscle aches that were thought to represent influenza; the remainder were described by patients as "colds."

Immunodot (Enzyme-Linked Immunosorbent Assay) of Plasma and Serum Samples

Fifteen serum samples were obtained from the 12 patients with a prodromal illness, 6 to 64 days (mean, 20 days) after the onset of the prodrome and 3 to 60 days (mean, 12 days) after the onset of GBS (Table). Nine samples were obtained from the five patients without a prodromal illness, 1 to 16 days (mean, 7 days) after the onset of GBS. Samples were stored at −20°C until serologic determinations were performed. Serum or plasma samples that were obtained from patients 6 to 15 days after the onset of gastroenteritis were considered to be positive if at least two of the three immunoglobulin classes demonstrated a titer of 400 or greater; serum

*GBS indicates Guillain-Barré syndrome; GI, gastrointestinal illness; and URI, upper respiratory tract illness. Day of onset of GBS was considered to be day "0."

or plasma samples that were obtained 16 to 64 days after the onset of gastroenteritis were considered to be positive if at least the IgG titers were 400 or greater.[9,10]

Immunodot assays of *C jejuni/coli*–specific IgG, IgM, and IgA antibodies were carried out by using the methods of Lior and Lacroix.[11]

Preparation of *C jejuni* Antigen Extracts

Antigen extracts of *C jejuni* serotype Lior 2 and *C coli* serotype Lior 12, found to give maximum heterologous reactivity with reference antiserum samples used for the serotyping of *Campylobacter*,[11] were prepared by the method described by McCoy et al.[12] Protein concentrations of the extracts were determined by the method of Lowry and colleagues.[13] Volumes of the two extracts that contained equal quantities of protein were pooled and lyophilized.

Determination of Properties of *C jejuni*

Serotyping of *C jejuni* was carried out by the method of Lior et al,[14] bacteriophage typing was done by the method of Grajewski et al,[15] biotyping was performed by the method of Lior,[16] and cytotoxic and cytotonic analyses were done according to the method described by Johnson and Lior.[17]

RESULTS

Three patients (Table, group 1) had serologic evidence of *Campylobacter* enteritis, with two of three antibody titers above 400. Samples from these three patients were obtained 51, 30, and 6 days after the onset of diarrhea and 47, 21, and 3 days after neurologic symptoms began. A second sample in patient 3 (Table), taken 5 days after the first, demonstrated slightly lower, but still elevated titers in all immunoglobulin classes. Each of the three patients with serologic evidence of infection had a severe gastrointestinal illness with diarrhea, and two (Table, patients 2 and 3) had *C jejuni* isolated from stool samples. The organism that was isolated from the stool of patient 3 (Table) was found to belong to serogroup 1, biotype I, and phage type 36; cytotoxic and cytotonic assays were negative.

Group 2 patients had some antibody titer elevation above 200, not high enough to make a serologic diagnosis of *Campylobacter* infection. Although the serum of patient 4 (Table) demonstrated an IgG titer of 400, this patient was not considered to have been infected with *C jejuni* because the other titers were low, and the prodromal illness was not gastroenteritis. Patient 5 (Table) did have mild gastrointestinal symptoms, but the plasma sample was obtained 14 days afterward, when the *C jejuni* serologic response usually peaks.[9,10] Instead, the IgM titer was only 400, with IgA and IgG titers below 100.

COMMENT

In this study, three of 17 consecutive patients with GBS had both clinical and serologic evidence of *C jejuni* infection and *C jejuni* was recovered from the stools of two patients. Failure to isolate *C jejuni* from a third patient was not surprising as the stool was obtained 47 days after enteritis.[18] The relatively low IgM and IgA titers in plasma samples that were obtained 51 days after diarrhea in this patient were consistent with data that showed that these titers decline, beginning 2½ to 4 weeks after infection, whereas IgG titers persist for longer.[9,10] Our group with only one class of titer above 400 was unlikely to have had recent *Campylobacter* infection.

The correlation among severe enteritis, positive *C jejuni*–specific serology, and the presence of *C jejuni* in stool in US patients is similar to the findings of Winer et al[8] in a study from the United Kingdom, but differs from the findings of two Australian studies.[2,7] The Australian series included larger groups of patients with GBS, of whom a high proportion (38% and 49%) were considered to have been infected with *C jejuni* on the basis of serologic findings alone.[2,7] Patients with and without gastroenteritis had serologic evidence of infection, but the organism was isolated from only two of 43 patients. The inclusion of our second group of patients with marginally elevated titers would make the proportion of *Campylobacter* that precedes GBS similar to some previous studies. The differences between our results and those of previous studies may also reflect different serologic techniques or differences between populations that live in different parts of the world. The series compiled by Winer et al[8] in the United Kingdom is similar to ours, with 14% of patients having had serologic evidence of *C jejuni*. However, the consistent finding of even a low incidence of *C jejuni*–infected patients with GBS reinforces the evidence that *C jejuni*, the only bacterial pathogen that regularly precedes GBS, has an incidence comparable with Epstein-Barr virus, cytomegalovirus, or *Mycoplasma* infection.[19,20] The incidence of prior *C jejuni* infection is probably lower than that reflected in our consecutive series, since six (35%) of 17 patients had a gastrointestinal prodrome. In contrast, only 10% of a larger prospective series,[21] and 17% in the United Kingdom series,[8] had a diarrheal illness. Additional studies on consecutive series of patients may allow a better approximation of the frequency and population variations of GBS preceded by *C jejuni* infection.

The recent finding of cross-reactivity between antigens from *C jejuni* and the P2 protein of peripheral nerve myelin may explain the pathogenetic connection between the infection and GBS[22] and possibly some of the marginally elevated titers in our second group of patients.

We thank the Health Research Training Program of the New York City (NY) Department of Health for providing their interns (Messrs Chan and Lee and Ms Molinaro) to assist with this project.

Autonomic Nervous Function in Progressive Supranuclear Palsy

J. Gert van Dijk, MD; Joost Haan, MD, PhD; Monique Koenderink; Raymund A. C. Roos, MD, PhD

• Autonomic nervous function was assessed in 11 patients with progressive supranuclear palsy, 26 patients with Parkinson's disease, matched for age, medications, disease severity, and disease duration, and 19 age-matched controls. Results of both parasympathetic (heart rate response to deep breathing and Valsalva maneuver) and sympathetic (blood pressure decrease on standing and increase on sustained handgrip) tests were abnormal in both patient groups. Abnormalities in the group of patients with progressive supranuclear palsy were similar to those in the group with Parkinson's disease but were more pronounced. Autonomic dysfunction may have to be considered a feature of progressive supranuclear palsy.

(*Arch Neurol.* 1991;48:1083-1084)

Autonomic dysfunction has not been considered a clinical feature of progressive supranuclear palsy (PSP).[1-3] The distribution of neuropathologic involvement in PSP reveals that several structures related to autonomic function are affected, such as the hypothalamus and the locus coeruleus.[1-4] We compared autonomic function in patients with PSP with that in healthy age-matched controls and patients with idiopathic Parkinson's disease (PD).

PATIENTS AND METHODS

Informed consent was obtained from all subjects, and approval was obtained from the local medical ethics committee. Diseases or medications affecting the autonomic nervous system were exclusion criteria.

Eleven patients with PSP were enrolled in the study (mean [SD] age, 75.5 [6.4] years; mean [SD] duration of motor symptoms, 3.5 [2.1] years; six patients were male). The diagnosis was based on established criteria[3]: a late-onset progressive nonfamilial disorder with supranuclear ophthalmoplegia and at least two of the following features: axial dystonia or rigidity, pseudobulbar palsy, bradykinesia, frontal lobe signs, and postural instability. As there is no specific disability scale for PSP, we used the Hoehn and Yahr[5] scale to express disease severity; six patients had stage III disease, and five had stage IV disease. Seven patients were being treated with levodopa, two with amantadine hydrochloride, and one with bromocriptine mesylate, alone or in combinations; four were taking no medication.

The patients were compared with 19 healthy age-matched controls (mean [SD] age, 74.3 [8.3] years; four subjects were male) and with 26 patients with PD (mean [SD] age, 73.5 [6.7] years; mean [SD] duration, 4.1 [4.0] years; 12 patients were male). Twelve patients with PD were taking levodopa, six were taking amantadine, and three were taking bromocriptine, alone or in combination; 12 were taking no medication. Two patients with PD had Hoehn and Yahr[5] stage II disease, 16 had stage III disease, seven had stage IV disease, and one had stage V disease.

Autonomic tests are influenced by age and possibly by antiparkinsonian drugs; some tests require physical and mental cooperation. Age, medications, and disease duration and severity were thus used as selection criteria for the PD group. Age and disease duration did not differ (Student's t test, $P=.5$) between the groups. The use of medication, as mentioned above, did not differ between the PSP and PD groups (χ^2 test, $P>.05$). The proportions of patients in Hoehn and Yahr disease stages did not differ (χ^2 test, $P=.59$).

The six autonomic function tests used have been previously described.[6] Heart rate variation was measured at rest, during forced breathing, on standing, and during a Valsalva maneuver. Maximum and minimum frequencies, derived from individual beat intervals, were used to calculate differences and ratios. Systolic and diastolic blood pressures were measured while the subjects were lying down and 1 and 2 minutes after they stood up. The pressure decrease was defined as the difference between starting and minimum pressures at 1 or 2 minutes. In the sustained handgrip test, blood pressure was measured every minute before and for 5 minutes after or until the subject gave up after the start of contraction. The difference between maximum and starting pressures defined the pressure increase.

Differences were investigated with analysis of variance and Student's t test. A significance threshold of $P<.05$ was used; values of $.05<P<.10$ were considered trends toward significance.

RESULTS

A consistent order of increasing abnormality (control, PD, PSP) was found for four of the six tests (Table, Figs 1 and 2). Statistically significant differences (by analysis of variance) were found for heart rate variation in the standing test and for blood pressure increase in the sustained handgrip test. When only the PSP and control groups were compared, the blood pressure response to standing also differed significantly.

COMMENT

We found evidence of sympathetic (blood pressure tests) and parasympathetic (heart rate tests) disturbances in patients with PSP compared with controls. Although not all comparisons resulted in significant differences, the consistent ranking of results in the order control, PD, and PSP suggests that this is explained by the limited number of patients or the large variability of test results (Valsalva maneuver and blood pressure to standing tests).

The autonomic dysfunction in the PD group is in line with earlier reports.[7-11] The pattern of abnormalities is similar in PSP and PD, suggesting that the same structures are damaged in PSP as

*Baseline heart rate is given as the mean rate of the resting test. Blood pressure (BP) values refer to baseline values in the standing test. Values are mean (SD). Significance levels are given for analysis of variance (ANOVA) and Student's *t* test; minus sign indicates $P > .10$; single asterisk, $P < .05$; double asterisk, $P < .01$; T, trend: $.05 < P < .10$.

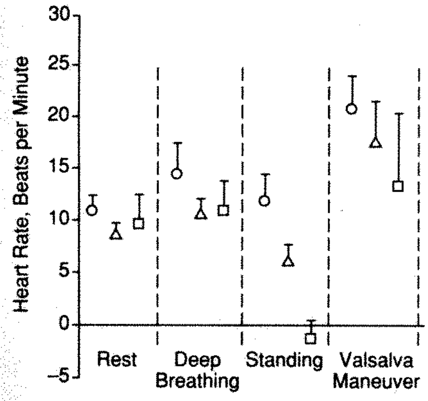

Fig 1.—Mean differences between maximum and minimum heart rates are illustrated for four heart rate tests and all three groups. Vertical bars indicate 1 SE; circles, control group; triangles, Parkinson's disease group; and squares, progressive supranuclear palsy group.

in PD, but more severely. Autonomic dysfunction in PD has been attributed to damage to the hypothalamus.[12,13] As damage to this structure also occurs in PSP,[14] this is a likely explanation for autonomic dysfunction in PSP as well.

Matching for medication makes it unlikely that the difference in severity was caused by medication. This is supported by studies in which no effect of antiparkinson treatment was found on autonomic function in PD.[7-9] An improvement of autonomic nervous function after levodopa treatment has in fact been documented.[11] Only dopamine agonist therapy appears to influence autonomic function,[10] but only one of our patients was taking this medication.

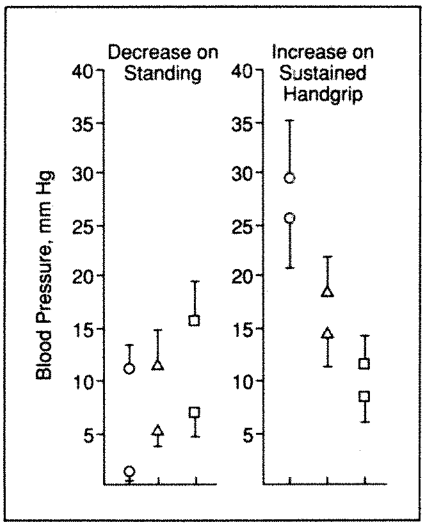

Fig 2.—Mean systolic and diastolic blood pressures are depicted for each of the three groups, for the standing and for the sustained handgrip tests. Vertical bars indicate 1 SE; circles, control group; triangles, Parkinson's disease group; and squares, progressive supranuclear palsy group.

The absence of dysautonomia has been proposed as a prerequisite for the diagnosis of PSP.[11] In view of our results, we suggest that dysautonomia may instead have to be included in the list of less constant and minor symptoms of PSP.

This study was supported in part by the Stichting Phoenix, Schiedam, the Netherlands.

“I have never gotten used to people dying. And I don’t want to get used to it.”

Dr. Aliza Lifshitz, Internist, Los Angeles, California, Member, American Medical Association

Patients come to physicians for many reasons. Beyond relief from pain, they seek compassion, empathy and support. AIDS patients receive all of these and more from Dr. Aliza Lifshitz.

Born and raised in Mexico and educated at one of Mexico City’s finest medical schools, Dr. Lifshitz now serves the Hispanic community in Southern California. Over a third of her patients have tested HIV positive. Most live below the poverty level. Many are illegal aliens.

“I never forget what it means to be a doctor, and what it means is embodied in the Principles of Medical Ethics of the American Medical Association (AMA),” states Dr. Lifshitz.

Dr. Lifshitz is a testament to what is best in medicine. She is also a member of the AMA. If you want to join her, return the attached postage-paid card or call 1-800-AMA-3211.

Acute Hemorrhagic Leukoencephalitis

A Successful Recovery

David Seales, MD, PhD, Melvin Greer, MD

• A 50-year-old woman developed acute hemorrhagic leukoencephalitis approximately 7 days after the onset of a benign respiratory infection. Mycoplasmal pneumonia was suspected because of Coomb's positive hemolysis, cold agglutinins, and sensitivity to erythromycin base but was not proved. Acute hemorrhagic leukoencephalitis was demonstrated by brain biopsy 24 hours after admission. The patient recovered without lasting sequelae following reduction of increased intracranial pressure by mannitol, hyperventilation, and phenobarbital and prolonged immunosuppression by plasmapheresis, steroids, and cyclophosphamide.

(*Arch Neurol.* 1991;48:1086-1088)

Acute hemorrhagic leukoencephalitis (AHL) was established as a pathologic entity in 1941.[1] This fulminant, myelinoclastic disease of the central nervous system is characterized by the development over hours to days of severe neurologic symptoms of confusion, dysarthria and/or aphasia, hemiparesis, seizures (focal or generalized), and, occasionally, acute myelitis. Fever, often remarkably high, may be present. Coma and death usually follow within a week. A prodromal illness (usually a viral upper respiratory infection) usually occurs days to 3 weeks before the onset of AHL, with apparent recovery.[2] Acute hemorrhagic leukoencephalitis was considered uniformly fatal, although survival has occurred in isolated cases treated with surgical decompression, corticosteroids, or plasma exchange.[3-5] The patient described herein was treated aggressively with plasmapheresis, corticosteroids, and cyclophosphamide and had intracranial pressure (ICP) monitoring. The patient recovered without residua.

REPORT OF A CASE

For 1 week, a previously healthy, right-handed, 50-year-old white woman had a cough and low-grade fever. Chest roentgenography revealed a diffuse interstitial infiltrate. The cough improved with oral erythromycin base therapy (500 mg every 6 hours). Seven days after the onset of her illness, the patient developed severe neck pain, occipital headache, and slurred speech. When discovered 8 hours later by her husband, she was lethargic and left-sided weakness was apparent.

In the emergency department 2 hours later, her blood pressure was 150/100 mm Hg; pulse rate, 92 beats per minute; respiration rate, 24 breaths per minute; and temperature, 37.8°C rectally. There was no nuchal rigidity. She picked aimlessly in the air. Intermittently, she would squeeze the examiner's hand in response to command; she squeezed with the right hand only. She opened her eyes to painful stimulation but did not speak. Her pupils were pinpoint (1.5 mm) but briskly reactive to light. Roving, conjugate, horizontal eye movements were present but alternated with a right gaze preference. Her mouth was held rigidly closed. She perceived pinprick diffusely as assessed by withdrawal and facial response. Strength (assessed during spontaneous movements) was reduced diffusely in the left hemibody (4/5 upper extremity; 4+/5 lower extremity). Tone was increased in the left upper extremity. Deep tendon reflexes were symmetrical and hyperactive diffusely. A Babinski's sign was present on the left.

A chest roentgenogram revealed a resolving left midlung field infiltrate. Computed tomography of the head before and after perfusion with contrast (Hypacque, 100 mL intravenous 60% solution) revealed a nonenhancing low-density area in the right frontal and parietal lobes, with a slight mass effect. Arterial blood gas analysis disclosed the following values: pH, 7.38; Pco$_2$, 44 mm Hg, Po$_2$, 45 mm Hg; bicarbonate, 25.3 mEq/L; and oxygen saturation, 77%. The white blood cell count was 23.2×10^9/L. The differential cell count was 0.76 polymorphonuclear leukocytes, 0.11 band cells, 0.06 lymphocytes, and 0.07 monocytes. Samples of the patient's blood held at bedside agglutinated at room temperature. Coomb's positive reactivity was noted with a cold agglutinin (titer 1:640). The agglutinin was not directed against the anti-I antigen on the red blood cell surface. Sedimentation rate (Westergren) was 25 mm/h.

Acyclovir sodium (loading dose, 1 g; maintenance dose, 700 mg every 8 hours), penicillin G potassium (2 million U every 4 hours), chloramphenicol sodium succinate (500 mg every 6 hours), and phenytoin sodium (loading dose, 500 mg; maintenance dose, 100 mg every 8 hours) were administered intravenously.

At 12 hours after admission, a nasal airway was placed because of increased upper airway obstruction with tracheal retraction. At 14 hours, there was coffee grounds emesis. At 15 hours, after experiencing difficulty with nasogastric tube placement, the patient was in respiratory distress (pH, 7.04; Pco$_2$, 71 mm Hg; Po$_2$, 30 mm Hg; bicarbonate, 19 mEq/L; and oxygen saturation, 34%. Endotracheal intubation was performed. Arterial blood gases returned to pH, 7.46; Pco$_2$, 28 mm Hg; Po$_2$, 158 mm Hg; and oxygen saturation, 99% (intermittent mandatory ventilation, 12 breaths per minute; positive end-expiratory pressure, 5 cm H$_2$O; and 50% oxygen).

Seventeen hours after admission, decerebrate posturing was evident in response to stimulation. The right pupil dilated (6 mm) and became nonreactive to light; the left pupil dilated to 3 mm and was sluggishly reactive to light. Ankle clonus and Babinski's signs were present bilaterally. Hyperventilation was begun. Mannitol (50 mg per intravenous dose), phenobarbital sodium (loading dose, 550 mg; maintenance dose, 250 mg/d), and dexamethasone sodium phosphate (Decadron, 6 mg per nasogastric tube every 6 hours) were administered.

Twenty-two hours after admission, erythromycin base (1 g administered intravenously every 6 hours) and ceftriaxone sodium (loading dose, 2 g; maintenance dose, 2 g administered intravenously every 24 hours) therapy was begun. Penicillin and chloramphenicol therapy was discontinued.

Brain biopsy was performed at the right frontal region 24 hours after admission. In white matter, there were microhemorrhages and focal acute fibrinoid necrosis of small vessels; the cortex was completely spared. Vacuolization, lymphocytes, polymorphonuclear leukocytes, and erythrocytes were present in perivascular white matter spaces. No inclusion bodies were seen, and stains for bacteria, acid-fast bacilli, India ink, *Toxoplasma*, herpes simplex, and fungi were negative. Acyclovir and ceftriaxone therapy was discontinued.

At the time of biopsy, an ICP monitor was inserted anterior to the site of the biopsy. The ICP remained elevated (16 to 19 mm Hg) for the second 24 hours of hospitalization. Thereafter, the ICP could be held between 10 and 15 mm Hg by the intravenous administration of mannitol (50 mg) when the ICP increased to 15 to 20 mm Hg. Arterial pH was maintained at 7.45 to 7.50 with the Pco$_2$ at 30 mm Hg.

The patient's neurologic status showed gradual improvement after 32 hours. Her

pupils were 1.5 to 2.0 mm bilaterally; her left pupil showed minimal response to light. Her oculocephalic reflex and corneal reflexes were still depressed. She was still hyperreflexic but no longer had ankle clonus. At 35 hours, a sternal rub elicited extensor posture.

The hematocrit dropped from 0.35 at admission to 0.16 thirty-six hours after admission. The drop in hematocrit was thought to be secondary to hemolysis (corrected reticulocyte count, 2.1%; total bilirubin, 32.3 μmol/L; direct bilirubin, 3.4 μmol/L). Packed red blood cells (2 U) were given. Intravenous methylprednisolone sodium succinate (Solu-Medrol) therapy (60 mg every 6 hours) was initiated.

At 36 hours, plasmapheresis (3 L exchange with a solution of 1500 mL of 5% albumin per 1500 mL of normal saline) was begun daily for 5 days. Electroencephalography revealed diffuse slowing in the anterior hemisphere (more pronounced on the left than on the right) consistent with encephalopathy. By 49 hours, the patient's pupils were 3 mm and reactive to light with presence of the oculocephalic response and bilateral corneal reflexes. The pharyngeal reflex was intact. Extensor posturing was still noted in response to pain. By 96 hours, extensor tone occurred in the extremities at rest. By 110 hours, eye movements fluctuated from oculocephalic reflex only to spontaneous, conjugate, roving eye movements. Ventilatory assistance was still required; spontaneous respirations were present only when the patient was stimulated. She still demonstrated extensor tone at rest but withdrew all four extremities to painful stimulation. She opened her eyes to sternal rub. By days 6 and 7, the presence of corneal reflexes was variable. Plasmapheresis was concluded on hospital day 7. By day 8, her eyes were deviated downward (left eye more than right). Her pupils were small and unreactive. Tone alternated between flaccid and rigid.

On hospital day 8, cyclophosphamide therapy (180 mg/d) was begun. Erythromycin therapy was discontinued. By hospital day 9, spontaneous respirations had returned, and the patient underwent extubation. Her neurologic status gradually improved. Purposeful eye movements occurred in response to verbal inquiry. Spontaneous movements of the body and then meaningful speech returned. Left-sided weakness resolved to a large extent.

A lumbar puncture on day 28 revealed the following values: opening pressure, 220 mm of cerebrospinal fluid with no red or white blood cells; glucose, 4.1 mmol/L; and protein, 0.28 g/L. Cerebrospinal fluid stains (India ink, acid-fast bacilli, and bacterial) and cultures (tuberculin, fungal, bacterial, and viral) showed no growth. Serologic tests were negative for cerebrospinal fluid, VDRL, and cryptococcal antigens.

Thirty-two days after admission, the patient was discharged. Mild recent memory impairment was evident. There were no deficits in immediate or remote memory. Orientation, judgment, content, affect, speech, reading, writing, naming, comprehension, left-right orientation, finger naming, calculation, buccofacial and appendicular praxis, figure drawing, mapping, stereognosis, and graphesthesia were intact. There was no neglect or perseveration. There was vertical diplopia (most marked with gaze to the lower left visual field) and mild weakness in the left hip flexors. Tone was increased in the left lower extremity. Cyclophosphamide had been given intravenously for 23 days (180 mg/d on days 8 through 10 and 12 through 24, tapered over the next 7 hospital days. The patient had received methylprednisolone sodium succinate (60 mg every 6 hours) on days 3 through 10 and oral prednisone (60 mg/d) on days 13 through 17 with tapering over days 18 through 39.

Follow-up computed tomographic scans of the head on hospital days 15 and 39 revealed reduced edema without cystic degeneration in the right frontoparietal regions. Acute and convalescent titers of mycoplasmal pneumonia, herpes simplex, rubella, influenza A and B, Epstein-Barr virus, parainfluenza III, equine encephalomyelitis, St Louis encephalitis, cytomegalovirus, and legionnaire's disease were negative for current infection. Tests were negative for human immunodeficiency virus. Six months after the onset of her illness, the patient resumed her previous employment. Four years later, the findings of her examination remained normal.

COMMENT

Approximately 70 cases of AHL are documented in the English language literature.[6-8] Both sexes are affected equally, with an age range of 2.5 to 60 years.[3] The lack of reported cases before approximately 3 years of age may relate to the incomplete myelinization of cerebral white matter before this age. A temporal relationship has been noted between certain common illnesses, such as upper respiratory infections, varicella, and bronchial pneumonia, and the subsequent development of AHL in the following days or weeks.[5] Acute hemorrhagic leukoencephalitis has also been noted following or in association with processes as diverse as removal of tooth stumps, herniorrhaphy, injection of pertussis vaccine, herpes simplex, thrombotic thrombocytopenic purpura, and application of arsphenamine to the gums.[3,9]

The incidence of AHL complicating atypical pneumonia is probably less than 0.1%.[10] Coomb's positive hemolysis and cold agglutinins are seen, especially in relation to *Mycoplasma pneumoniae* infection.[11]

In the present case, infection with *M pneumoniae* was suspected, but acute and convalescent titers were negative. Furthermore, the cold agglutinins did not react with polysaccharide antigen expressed on the surface of adult erythrocytes as is noted in mycoplasmal pneumonia. No other viral titers were positive for current infection. Thus, the precise nature of the atypical pneumonia in the present case is unknown.

The differentiation of AHL from herpes simplex encephalitis can be difficult. Fever, headache, hallucinations, focality of neurologic abnormalities, and acuteness do not differentiate the two diseases. Examination of cerebrospinal fluid may exclude bacterial, fungal, and mycobacterial infection but will not differentiate AHL from herpes simplex. Thus, early brain biopsy is advocated. In AHL, necrotizing angiitis of venules and capillaries of white matter is noted microscopically. Gray matter and subcortical U-shaped fibers are usually spared as opposed to the gray and white matter damage observed in herpes simplex encephalitis. In AHL, ball-and-ring hemorrhages form around affected vessels, with fibrinoid necrosis and polymorphonuclear leukocytes evident in vessel walls. Later, lymphocytes replace the polymorphonuclear leukocytes; lipid phagocytosis is seen if survival is several days. Grossly, the lesions are usually unilateral in the parietal or posterior frontal regions, but may be bilaterally symmetrical. Lesions can occur in other regions as well, including the brain stem and spinal cord.[2,3]

The lesions of AHL can be demonstrated by computed tomography.[12] Furthermore, it has been proposed that with computed tomography one may be able to distinguish between AHL and herpes simplex encephalitis.[13] This is based on the findings that in AHL the computed tomographic findings arise earlier (in 1.5 days as opposed to 3 to 11 days for herpes simplex), are restricted to white matter, and do not enhance with contrast.

The pathogenesis of AHL is unknown. An immunoreactive basis is supported by (1) the latent period between preceding illness and onset of AHL, (2) the lack of identification of an infecting organism, (3) the relation to immunization, (4) the atopy observed in many patients with AHL, and (5) the similarity to a fulminant form of experimental allergic encephalitis.[2] In animals, experimental allergic encephalitis is a model of acute disseminated leukoencephalitis; it is also a white matter myelinoclastic process but of less acute course than AHL.[14] In addition, DNA-synthesizing lymphoblasts have been observed in the peripheral blood of a patient with AHL, as well as in animals with experimental allergic encephalitis.[15]

Success in the treatment of AHL has been modest. Two of five proved cases survived following surgical decompression.[16] High-dose steroids (10 mg of dexamethasone administered intravenously, then 6 mg every 6 hours) have been thought to aid in the survival of patients with AHL.[3,4] More recently, plasma exchange was used successfully in one patient with neurologic sequelae of mycoplasmal pneumonia.[17] Until now, to our knowledge the use cyclophosphamide has not been reported in the treatment of AHL. Its effect in this patient remains uncertain. Effective treatment probably consists of a combination of early diagnosis based on clinical suspicion, neuroimaging, brain biopsy, life support with reduction of elevated ICP in the critical stage, and early, sustained treatment with appropriate immunosuppressants.

Isolated Congenital Hemianopia Caused by Prenatal Injury to the Optic Radiation

Nicola K. Ragge, MRCP FCOphth; A. James Barkovich, MD;
William F. Hoyt, MD; Scott R. Lambert, MD

• Isolated congenital hemianopias are typically caused by developmental abnormalities of the occipital lobe cortex. We describe two patients with an incidental partial hemianopia associated with unilateral periventricular leukomalacia that was acquired prenatally. Magnetic resonance imaging scans suggest a late second or early third trimester unilateral cerebral ischemic event.

(*Arch Neurol.* 1991;48:1088-1091)

Isolated congenital occipital lesions with accompanying hemianopia usually involve gray and white matter. Examples include porencephaly[1-3]; vascular malformations, either isolated or in association with Sturge-Weber–type malformation without cutaneous signs[4]; colpocephaly[5]; and polymicrogyria of the striate cortex.[6,7] This report documents two cases of congenital hemianopia caused by prenatal injury to the periventricular white matter.

REPORT OF CASES

CASE 1.—A healthy 21-year-old white woman was found to have an inferior quadrantic field defect during a routine eye examination. She had a history of herpetic keratitis in her right eye. There was no history of prenatal or postnatal illness or neurologic disorder. Her visual acuities were 20/50 in the right eye and 20/20 in the left eye. There were no abnormalities of color vision. Her pupil reflexes were equal bilaterally. Both Goldmann and computerized visual field testing showed a right inferior homonymous quadrantanopia with minor incongruity along the horizontal meridian (Fig 1). There were signs in both retinas of nerve fiber loss corresponding to that seen in homonymous hemioptic atrophy.[8] Both discs were small in diameter. The right disc showed band atrophy, with loss of nerve fiber layer especially prominent at the nasal disc edge, where the pigment epithelial edge could be seen. The superior and inferior arcuate bundles were well preserved. On the left disc, a full complement of nasal nerve fiber layer could be seen, but temporal pallor and relative loss of the superior and inferior arcuate bundles

Fig 1.—Patient 1. Right inferior homonymous quadrantic defect demonstrated by Goldmann perimetry.

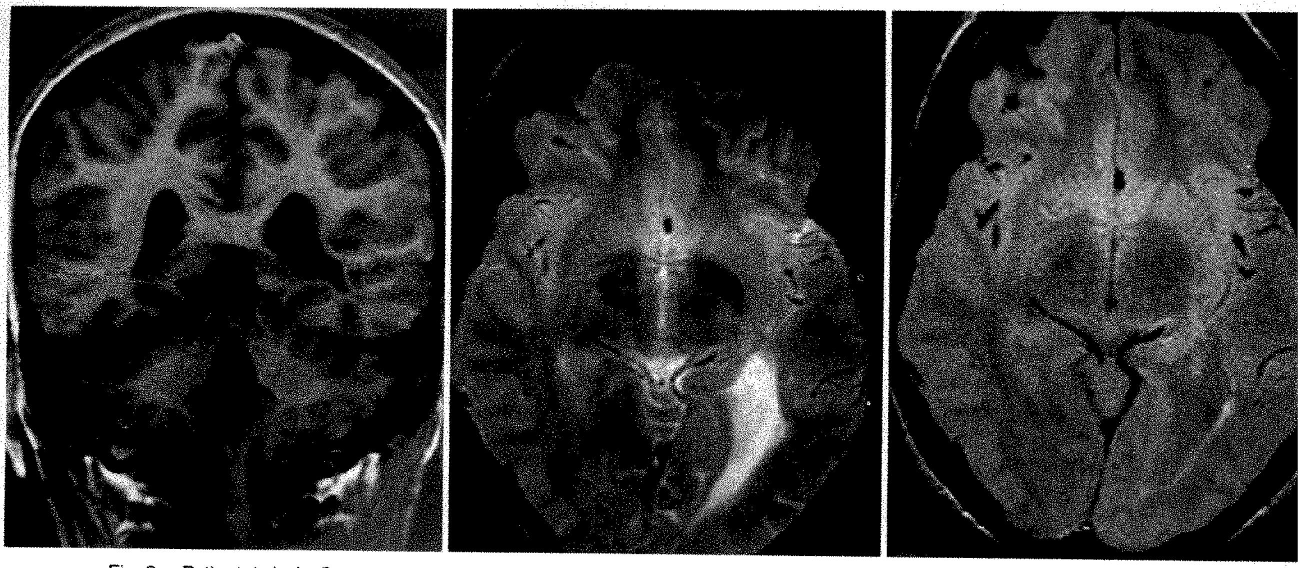

Fig 2.—Patient 1. Left, Coronal T_1-weighted image at the level of the ventricular trigone shows a nearly complete absence of periventricular white matter inferolaterally on the left. The depths of the cortical gyri nearly abut the ventricular surface. Center, Heavily T_2-weighted axial image shows the expanded trigone and paucity of periventricular white matter. The lateral margin of the ventricle is poorly defined. Right, Spin-density image at the same level as center shows high signal intensity in the periventricular white matter, representing damaged tissue. The presence of this area of high intensity indicates that the damage occurred later than that in patient 2 (compare with Fig 4, right).

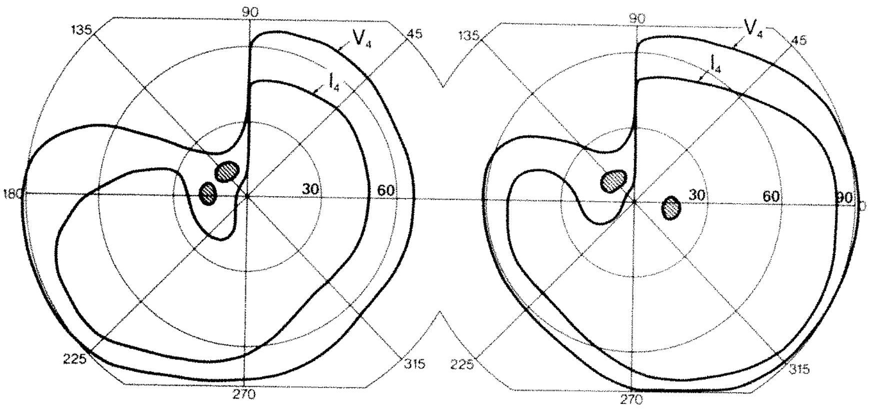

Fig 3.—Patient 2. Left superior homonymous quadrantic defect demonstrated by Goldmann perimetry.

were present.

Magnetic resonance images of the brain (Fig 2) showed ex vacuo enlargement of the trigone and occipital horn of the left lateral ventricle. The close approximation of the cortical gyri, particularly the posterior insular cortex, to the ventricular surface was characteristic of the pattern seen as a result of loss of the intervening white matter. In this location, the white matter is partially composed of the optic radiations. T_2-weighted images showed a thin strip of high signal intensity in the immediate periventricular white matter indicative of replacement of normal tissue by gliotic white matter.

Case 2.—A healthy 10-year-old black boy, vho was being followed up in the eye clinic 'or a left esotropia and amblyopia, was found o have a left homonymous hemianopia. 'here was no significant obstetric or perina-al history. His visual acuities were 20/25 in ie right eye and 20/200 in the left eye. The pupils were 3 mm in diameter, equal, and fully reactive. There was a mild left relative afferent pupillary defect. The patient had a left superior homonymous quadrantanopia (Fig 3). The retinal nerve fiber layer demonstrated a pattern of nerve fiber loss indicating homonymous hemioptic atrophy.[8] The remarkable feature of both discs was that they were large in diameter, with pronounced physiological cups and a nasal entrance of the vessels. The left disc was vertically oval and kidney shaped with band atrophy. There was an atrophic nerve fiber layer at the nasal border of the left disc compared with a full nasal nerve fiber layer adjacent to the right disc.

Computed tomography of the head showed enlargement of the right lateral ventricle, most notably the trigone, as a result of loss of periventricular white matter. Magnetic resonance imaging with gadolinium-pentetic acid (Fig 4) showed the same enlargement of the ventricle and more clearly showed t close approximation of the depths of the c tical gyri to the ventricular wall. T_2-weight images showed normal intensity of the pe ventricular white matter. No enhanceme was seen after administration of intravenc contrast.

COMMENT

We have described two cases of u lateral white matter injury in the regi of the optic radiations causing isolat partial hemianopias. In both cases t ophthalmologic evidence of transsyna tic nerve fiber degeneration establish the occipital injury as a prenat event.[8,9] The occurrence of such notic able retinal nerve fiber layer and opt disc changes is somewhat unexpecte the predicted loss of nerve fibers l transsynaptic degeneration from a l sion that causes a quadrantanop would be about 25% from each opt nerve. We have no explanation for t fact that both patients' homonymou field defects were quadrantic, while t magnetic resonance imaging sca showed diffuse, not focal, thinning the visual radiation in the involved o cipital lobes.

The affected regions of both brai have magnetic resonance imaging cha acteristics that fit those reported f end-stage periventricular leukomal cia.[10,11] These are (1) ventriculomegal sometimes with irregular outline of th ventricular surface; (2) reduce amounts of periventricular white ma ter at the trigone and, in more seve cases, the entire centrum semiovale; (

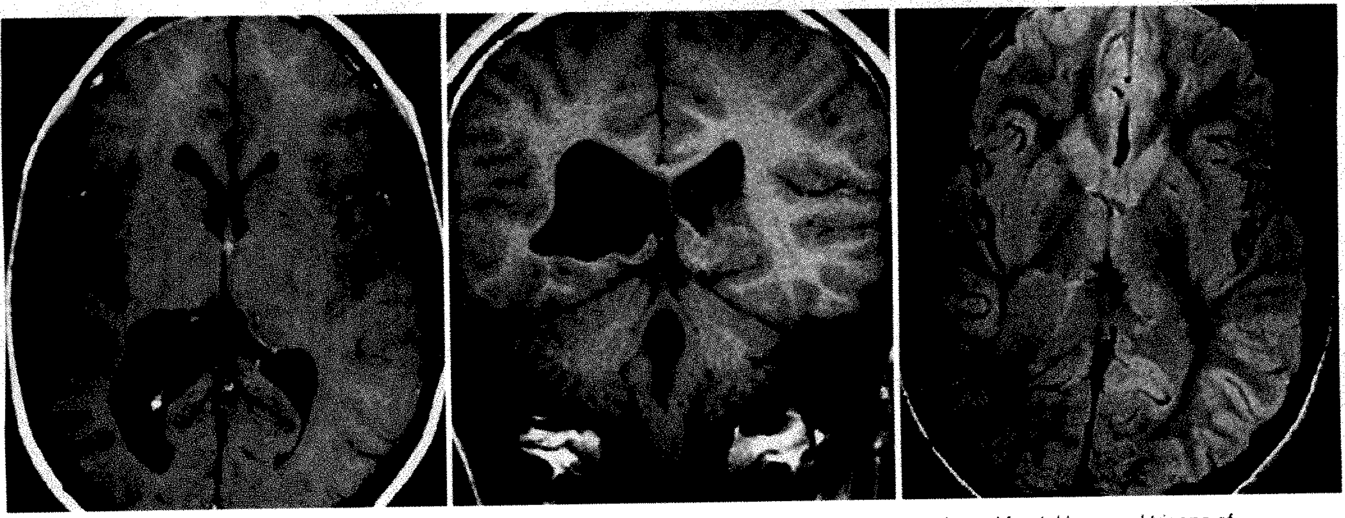

Fig 4.—Patient 2. Left, Axial T_1-weighted image after infusion of intravenous contrast shows enlarged frontal horn and trigone of the right lateral ventricle. Note the paucity of white matter between the cortical gyri and the ventricular surface on the right side compared with the left. No contrast enhancement is apparent. Center, Coronal T_1-weighted image at the level of the ventricular trigones shows that the absence of periventricular white matter is more marked inferiorly at the level of the optic radiations. Right, Axial spin-density image at the level of the ventricular trigones shows an absence of high signal intensity in the periventricular white matter (compare with Fig 2, right). This implies an earlier gestational event.

deep and prominent cortical sulci with subcortical white matter approaching the ventricles with little interposed white matter; and (4) prolonged T_2 relaxation time in the immediate peritrigonal white matter, sometimes extending anteriorly along the ventricular body.

Periventricular leukomalacia occurs most commonly in premature infants who also have other complications including hyaline membrane disease, persistent fetal circulation, and germinal matrix hemorrhage.[12,13] Both pathological and neuroimaging studies have shown a characteristic progression that begins with edema, followed by coagulation necrosis and eventually cavitation, usually in 3 to 6 weeks.[12-14] The cysts usually collapse, the affected brain exhibiting gliosis and reduction in the quantity of white matter in the periventricular region. The ependymal separation between the cavities and the ventricle may break down, with consequent incorporation of the cavities into the ventricle.

Since periventricular leukomalacia occurs most commonly in the peritrigonal region,[15] through which the geniculocalcarine radiations course, it is not surprising that patients with this condition commonly have visual impairment.[16,17] However, this is usually seen in the context of a premature infant with bilateral defects. Several authors have described unilateral periventricular leukomalacia[18-21]; however, all have concentrated on motor dysfunction and none have described visual impairment.

The pathogenesis of most cases of periventricular leukomalacia is now widely accepted as being the result of ischemia in the immature brain.[11,22,23] The "watershed areas" of the premature brain are located in the periventricular region.[24] At about 36 weeks' gestational age, the watershed areas begin to move peripherally, eventually reaching the subcortical white matter and cerebral cortex at term. It is a logical extension of this concept to postulate that unilateral periventricular leukomalacia is most likely to be the result of in utero hypoperfusion of a single hemisphere.

Gilles et al[25] have shown that the glial response to brain injury is minimal prior to about 26 weeks' gestational age. Barkovich and Truwit[11] have further shown that asphyxic brain injury prior to 28 weeks' gestational age shows minimal periventricular T_2 prolongation. The area of prolonged T_2 relaxation time adjacent to the enlarged trigone in patient 2 indicates an injury between about 28 and 34 weeks' gestational age, whereas the absence of periventricular prolonged T_2 relaxation in patient 1 indicates an earlier injury, most likely during the second half of the second trimester.

This study was supported, in part, by grants from the Wellcome Trust and the Royal Society of Medicine, London, England. Dr Ragge is a Keeler Scholar, Keeler Ltd, Windsor, England.

Visual Hallucinations and Racing Thoughts on Eye Closure After Minor Surgery

C. Miller Fisher, MD

• Two hours after minor surgery under local anesthesia, a 67-year-old man developed vivid visual hallucinations that were present only when he closed his eyes. After lasting 4 hours, the hallucinations were succeeded by racing thoughts, lasting 2 hours, and then by illusionary movements of his body. The reaction was attributed to the effect of lidocaine. The case resembles one previously reported.

(*Arch Neurol.* 1991;48:1091-1092)

The occurrence of visual hallucinations on eye closure in a fully alert patient is a rarely reported phenomenon. Recently, one case was described in which the hallucinations were attributed to atropine toxicity and lasted 11 days.[1] The present case bears a close resemblance; but, in addition to visual hallucinations, the patient experienced "racing thoughts" (his term) and hallucinations of body movement on eye closure. The symptoms began shortly after a minor operation that was performed under local anesthesia.

Abnormal mental events are of interest, not only as they aid in clinical interpretation, but also as they extend our knowledge of the brain's behavioral capability.

REPORT OF A CASE

A 67-year-old hypertensive physician reported a 15-minute spell of weakness of the right side of the face and the right hand. Results of neurological examination were normal, as was a cranial computed tomographic scan. Angiography showed stenosis of both internal carotid arteries to less than -mm residual lumen, worse on the right side. A right-sided carotid endarterectomy was attempted, but patency could not be restored, and the internal carotid artery was ligated. Immediate recovery was uneventful; but, 24 hours later, on removing the drain from the wound, bleeding occurred into the neck, forming a mass that displaced the trachea. The blood clot was promptly evacuated using 15 mL of 0.01% lidocaine, with 0.005% phenylephrine hydrochloride as the local anesthetic. The only additional medications were codeine, 60 mg, given orally 2 hours before the operation; cefazolin sodium, 1 g; and labetalol, 5 mg, administered twice during the procedure, which was uncomplicated and lasted about 1 hour. Cerebral hypoxia did not occur. The labetalol temporarily replaced atenolol, which the patient had been taking for about 6 years.

At 12:30 PM, two hours after surgery, while drowsing, the patient began to experience visual hallucinations; these continued for about 4 hours. According to his daughter, who sat at his bedside as he described the events to her, he was lucid and appropriate at all times. He was first seen by me a few hours after the aberrant ideation had ceased; at this time, his memory of the happenings was still fresh.

The visual hallucinations consisted of four main topics: books and other printed material, street scenes, snowy landscapes, and animals of many kinds. The images followed one another in quick succession, "nonstop with no rhyme or reason," each one lasting 2 or 3 seconds. When he opened his eyes, the visions disappeared. Although he was wide awake and apparently clear mentally, it was for some reason difficult to keep his eyes open. "It was as if they were being forced shut." He was not frightened or alarmed, but was restless and unduly excited; he attributed this to a feeling of being out of control and helpless. The images were colored and projected into the center of space before him, without lateralization. They were silent, and figures showed no facial movements to suggest that they were speaking. The individual hallucinations were entirely unrelated to one another, with no recognizable narrative connection. It was broad daylight, and the room was brightly lit.

The printed matter consisted of books and pages; in addition, handwritten material was present. The colored street scenes were not recognized as being in any particular city; many people about 1 m tall were rushing across the street from side to side at great speed, dashing hither and thither, creating a bewildering confusion. The streets were lined with buildings on each side. The people seemed to be further away than the surroundings, creating the appearance of miniaturization. There were no autos. The snow scenes stretched for miles over low hills. As the hospitalization was in the winter time, when there was snow, this may have been a determining factor; but, a snow scene could quickly be followed by one without snow. There were no trees. The animals were deformed and repugnant; for example, there were ugly, one-eyed Picasso-like monsters, or, grotesque, nongeometrical shapes that were everchanging. The animals were stationary, as in a picture. There were no recognizable normal animals, such as dogs, cats, horses, or rodents. The coloring was mostly of water colors and pastels, except for white, which was quite bright, and orange, which was vivid.

As the visual hallucinations subsided, they were followed by a most unpleasant episode of "racing thoughts." The patient was not aware of any visual or auditory images. Unconnected thoughts followed one another in quick succession, without any sense. They passed so swiftly, the patient was unable to recognize them. It was his impression that they were about people, rather than things or places. They probably involved family members, including a grandson. Each thought might consist of three staccato bits, only to be interrupted by an entirely different thought with its own few bits, with the whole series being fragmentary and meaningless. Also, the thinking spree was present only when his eyes were closed; this was immediately dispelled on opening the eyes; but, again, there was difficulty in keeping the eyes open in the absence of sleepiness. The episode of rushing thoughts was stranger and more unpleasant than the visual hallucinations, although the thoughts themselves were not frightening or bizarre. The patient agreed that the thoughts might have been ordinary thinking, speeded up to a dizzying degree. In light of the patient's statement

that his "racing thoughts" were without visual or auditory imagery, the presence of imagery during normal thinking was discussed with him. He concluded that the thoughts passed and changed so rapidly that analysis was impossible. The "racing thoughts" preempted his mind, precluding any parallel thinking on his own.

In the minutes following cessation of the "racing thoughts" that had lasted about 2 hours, the patient had the sensation that both he and his bed were moving along in the direction of the foot of the bed. Alarmed, he would open his eyes and seize the side rails of his bed, whereupon the feeling of movement stopped. The bed was involved in the movement, and not just the patient; nevertheless, the act of holding on (or opening the eyes) stopped the sensation. He thought the movement resembled his being taken to the operating room on a stretcher; that is, the speed of the motion was similar. Each time he closed his eyes, the sensation recurred. This lasted for 30 minutes to 1 hour.

The patient was aware that all of the phenomena described were in his imagination and not real. He opened his eyes deliberately and looked around to be sure that this mind was clear. According to his daughter, his speech was normal. The patient's neurologic examination results were normal, both before and after the surgical procedure. His memory of the details was quite intact, indicating that the hippocampal memory system was recording events. The visual hallucinations were highly complex, evidence that the visual association cortex maintained a high-level performance.

COMMENT

A previous article[1] reported the occurrence of visual hallucinations associated with eye closure in a patient with atropine toxicity. The visual hallucinations in the present case were much the same—present on eye closure and consisting of a rapid succession of unrelated images, faintly colored, and silent. The two cases probably represent the same process. In the atropine case, the hypothesis was advanced that if a parallel with any recognized normal neurologic phenomenon was to be drawn, it was with the hypnagogic hallucinations of sleep onset. It was speculated that the hallucinations were the result of a primary disturbance in the sleep-awake apparatus of the brain stem—in particular, in the rapid eye movement system of the pontine tegmentum. Support for the hypothesis was limited to clinical observations—the crucial importance of eye closure, a disturbance of sleep, excessive dreaming, and the presence of a dreamlike quality in some of the visual hallucinations. In the present case, the entire abnormal period lasted only 7 hours, although the patient may have slept in the interval between completion of surgery and the onset of hallucinations. When asked why he closed his eyes rather than keeping them open, thus preventing the imagery, the patient's answer was of some interest. His explanation was that for some reason it was difficult to keep them open. Eye closure is a central feature of the syndrome, and if in some way it is "forced," a relationship with sleep would be strengthened.

Besides visual hallucinations, the present patient had the two additional features: racing thoughts and illusions of movement, occurrence of which was also strictly related to eye closure. It may be presumed that these features share a common or closely related origin with the visual hallucinations and that all three are analogous manifestations. The racing thoughts showed the same nonstop rapid turnover of unrelated items, as did the visual hallucinations. Racing thoughts and illusory movement are not described in hypnagogic experience,[2] and racing thoughts do not occur in dreaming. In this regard, the stated hypothesis is weakened.

The symptom of racing thoughts is rare in neurology. The manic phase of manic-depressive illness may bring a "press of speech and ideas." Schizophrenics may show the same trait, but whether there is any parallel with the present symptom requires further observation. The records of the Massachusetts General Hospital Stroke Service contained notes on one patient whose story may be relevant. A 50-year-old man with an upper respiratory infection and a temperature of 40°C reported visual hallucinations of objects, buildings, and magnificent cathedral arches on closing his eyes. The images lasted only 1 to 2 seconds, were in black and white, full size, and about 6 m distant. The images seemed to change or shift when the eyes moved beneath the closed lids. They were always superimposed on a grid or meshwork containing interstices, but not a woven texture. There was no sound or color. The hallucinations disappeared on opening the eyes. Also, on closing the eyes, the patient had what he called, "forced ideas," in which he thought about things that were foreign to him, as well as threatening. He said "they were vivid dreams, but not visual."

Just as visual hallucinations, in view of their complex nature most likely arise in the visual association cortex, racing thoughts must be a cortical phenomenon, localized probably in the association areas of the dominant parieto-occipital region. In keeping with this, is the occurrence of brief runs of racing thoughts in partial complex seizures of temporal lobe origin.

The term *illusionary movement* used for the patient's third symptom is probably inaccurate, for the sense of motion with the eyes closed was a false perception; therefore, this qualifies as a hallucination, rather than as an illusion. A false sense of turning or rocking is common in labyrinthine disorders when the eyes are closed, but the occurrence of a well-patterned discrete motion, such as our patient described, is outside our personal neurologic experience. The nature of the false-linear motion of the body and its locus within the nervous system are quite unknown. By analogy with the other two symptoms, a cortical origin would be suspected.

Whereas atropine was held to be the responsible agent in the previous case, it was not a factor here. Lidocaine is commonly associated with sleepiness and confusion,[3] and it must be the primary suspect. Labetalol in two doses of 5 mg can hardly be incriminated, although β-adrenergic blockers can cause confusion.[4] Cefazolin is not known to be toxic to the central nervous system. Phenylephrine in very small doses is an unlikely offender. At the same time as a toxic effect of medication is emphasized, it is to be recalled that in the supplementary case described, infection and fever produced a somewhat similar syndrome. It is of interest that one of the main adverse effects of lidocaine is drowsiness, reflecting an action in the sleep-awake system, wherein, by present postulate, the patient's symptoms arose. If that is true, the clinical picture illustrates the principle that toxic manifestations originate within a distinct functional subsystem of the brain, here, the sleep-awake subsystem.

One other point warrants comment, namely, the visualization of printed and written material in hallucinations. Whereas in the present case no meaning could be discerned, in the previous case, the patient thought he recognized words and meaning; but, on peering closely, the letters became nondescript markings and, finally, disappeared altogether. Meaningful print and script do not appear in dreams, indicating that the brain cannot display from memory preformed written material that can be visualized.

Professional Opportunities

KANSAS — Board-certified, board-eligible neurologist to join child neurologist in rebuilding a three-person practice in the largest city in Kansas. Three large, well-equipped hospitals available for resident and undergraduate medical education. Located in clean, progressive community described as the franchise capital of the country. Competitive salary and benefits available. Send CV to: Richard C. Gilmartin, MD, 2620 East Central, Wichita, KS 67214.

MAUI ORTHOPEDIC and Sports Medicine seeks neurologist to establish independent practice. Contact: William Gfeller, 450 Hookahi Street, Wailuku, Maui, HI 96793. (808) 244-5541.

ADULT NEUROLOGIST to associate with two separate, busy solo neurologists. Practices are referral based, with two separate offices and three voluntary hospitals. Successful candidate would be expected to develop a separate solo, but collaborative practice. Established physicians would expect to provide substantial support for beginning physician. Opportunity would provide for cross coverage and joint venturing of facilities. Successful candidate should have excellent clinical skills. The medical community has excellent neurophysiology, neuroradiology, and neurosurgery. Located in a medium size city with both excellent living conditions and an extremely solid economic base. Please contact: Jeffrey A. Ribner, MD, 503 Plaza Drive, Vestal, NY 13850. (607) 729-1521 or Robert R. Taylor, Jr., MD, 269 Riverside Drive, Johnson City, NY 13790. (607) 798-7143.

CAROLINA — PIEDMONT: BC/BE adult neurologist to join two neurologists in busy clinical practice. All neurodiagnostics available. Salary leading to partnership. Position available immediately. Send CV to: Marilyn Miller, 145 Dillon Drive, Spartanburg, SC 29302.

MELBOURNE, FLORIDA — Outstanding opportunity for an adult neurologist who would like to join a group of nine neurologists. Our group includes child neurologist, neuromuscular specialists and neurorehabilitation specialists. We live in a beautiful, high tech, beachside community with great schools and affordable housing. Please send CV to: Search Committee, P.O. Box 693, Melbourne, FL 32902.

NEUROLOGIST — Beautiful Durango, Colorado is recruiting a BC/BE neurologist: Mercy Medical Center is an extremely progressive and active 100-bed facility and is doing well financially and growing — primarily due to an excellent staff of 90 physicians and a decent economy. Durango is located in southwestern Colorado, with an abundance of outdoor recreation (skiing, fishing, hunting, bicycling) excellent restaurants, an excellent local 4-year college, great weather and excellent schools! For more informaion about this excellent practice opportunity, mail CV or call: Bob Conrad, Vice President, Mercy Medical Center, 375 East Park Avenue, Durango, CO 81301. (303) 247-4311.

INDIANAPOLIS METROPOLITAN AREA: Young and aggressive Indianapolis neurological group seeks board-eligible or -certified associate. Broad spectrum of clinical experience is important. Experience in EEG, evoked potentials and EMG is necessary. Sub-specialty training is desirable, but not necessary. Indianapolis is a desirable, growing, clean and safe community. Excellent salary plus bonus and beneifts leading to partnership opportunity. Send CV to: Midwest Neurological Insitute, 998 East Main Street #202, Danville, IN 46122.

PLEASE NOTE—Address replies to box number ads as follows: Box number ______, c/o AON, P.O. Box 1510, Clearwater, FL 34617.

300 N. Eisenhower Avenue
Mason City, IA 50401
(515) 423-2435

Professional Opportunities

CHARLOTTE, NORTH CAROLINA: High quality group of five neurologists, all of whom are subspecialized, seeks to add a well-trained specialist. Contact: Mike Kaufman, MD, 1900 Randolph Road, Suite 1010, Charlotte, NC 28207. Or call: (704) 334-7311.

NEED A DOCTOR? For the most comprehensive coverage to specific specialties and select subspecialties, put your recruitment ad in an AMA specialty journal. We target your ad to the physician you want. To schedule your ad call our "Classified Advertising" office: (800) 237-9851.

NEUROLOGIST — BC/BE to join main branch of thirty-five physician multi-specialty group. Excellent clinic and hospital facilities. Very competitive salary and benefit package. Excellent opportunity. Good hunting, fishing. Good schools, a beautiful place to raise a family. Call Executive Administrator collect (701) 857-0236, or write: Medical Arts Clinic, PC, P.O. Box 1489, Minot, ND 58702-1489.

EXCELLENT OPPORTUNITY for BC/BE neurologist to join 80-physician comprehensive, multispecialty group in San Francisco Bay Area. Large, varied referral base from Pediatrics, IM, FP, and Surgery. EMG/NCV, EEG, Evoked Response Testing, CT, MRI, Radiology support all available on site. Opportunity to interface with specialists of all types including neurosurgeons. Major university teaching affiliation encouraged and possible. Close proximity to 400-bed full service, modern hospital serving population of 300,000. Competitive guaranteed salary with bonus productivity plan for initial 18 months leading to partnership track. Extensive benefit package including housing incentives. Unique cultural, recreational and educational opportunities. Send CV to: Gary D. Zweig, MD, Recruitment Chairman, Sunnyvale Medical Clinic, P.O. Box 3496, Sunnyvale, CA 94088-3496.

OCHSNER NEUROLOGIST — The Ochsner Clinic of Baton Rouge seeks qualified neurologists to expand its department in our multi-specialty regional clinic. The practice offers an opportunity to practice in a setting which supports innovation and involvement in education and research. Competitive salary and excellent fringe benefits program. Send CV to: Ochsner Clinic of Baton Rouge, Physician Recruiting Support Services, 16777 Medical Center Drive, Baton Rouge, LA 70816; or call: (800) 488-2240.

NEUROLOGIST: Urban area in North Carolina. BC/BE, to join solo neurologist in a rapidly expanding, progressive and active practice. All neurodiagnostic modalities available. Excellent salary leading to partnership. Experience in EMG, EEG and EPs. Please reply with CV to: Box #822, c/o AON.

EXCELLENT OPPORTUNITY for BC/BE neurologist to practice in large eastern metropolitan area. Opening for July 1992 or earlier, for private practice with geographic full-time appointment at large teaching institution. Medical school appointment, teaching and research opportunities. Subspecialty in movement disorders, muscle diseases or neuro-oncology preferred but not required. Submit CV to: P.O. Box 5849, Pittsburgh, PA 15209-0849.

NEUROLOGIST: BC/BE neurologist to join established neurologist or establish independent practice with shared call and negotiable reimbursement options. Progressive midwestern community hospital close to several academic institutions and with attractive recreation options. Contact: B. Sisman, MD, (313) 242-6030.

NEUROLOGIST — Reynolds Army Community Hospital, Fort Sill, Oklahoma is currently seeking BE/BC neurologist. Opportunity to practice in new state-of-the-art clinic office/hospital setting. Competency in EEG/EMG required. CAT scan and MRI interpretation experience desirable. No capital investment required. Compensation is negotiable depending on applicant's qualifications. Information, application forms and instructions for applying may be obtained by calling or writing the: Department of the Army, Commander, USAMEDDAC, Attention: HSUA-CAM, Major Condra, Fort Sill, OK 73503-6300. Telephone number: (405) 351-4021/2418.

Professional Opportunities

THE OCHSNER CLINIC in New Orleans is seeking a BE/BC neurologist with fellowship-training in neuromuscular disease. The candidate should have strong clinical skills in the diagnosis and management of both peripheral nerve and muscle disease. Experience in interpreting nerve and muscle biopsy is also required. It would be preferred yet not essential that the physician be able to perform the actual biopsy. The Ochsner Clinic is a large (250 MDs) multi-specialty clinic with an adjoining 500-bed hospital. The neurology service is affiliated with the Tulane University Neurology Department and our staff have clinical appointments at Tulane University. The neurology service has teaching responsibilities at the Ochsner Foundation Hospital for Tulane neurology residents, Ochsner medicine residents, Louisiana State University Rehabilitation residents, Ochsner interns and Tulane medical students. At Ochsner there are also opportunities for individual and cooperative clinical research. Interested physicians should send a complete CV to: Dr. Richard L. Strub, Chairman, Department of Neurology, Ochsner Medical Institutions, 1514 Jefferson Highway, New Orleans, LA 70121. For more details, please call: (800) 488-2240.

NEUROLOGIST — San Francisco, Lake Tahoe and Reno are just 90 minutes away. Neurologist to join one other in busy and diverse practice. The groups well established referral network of 45 physicians and surgeons will insure volume and variety of cases. Department is equipped with EMG, EEG, and CT. Sacramento is a brief 35 minute drive. For complete details: Gerry Myers (800) 368-2416, Extension 107.

GREAT LAKES! Well-established, rapidly growing neurology practice seeks additional BC/BE neurologist. Charming community in area nationally recognized for medical excellence. Country lifestyle yet easily accessible to major metropolitan area. State-of-the-art facilities; good patient mix; coverage from BC neurologists; financial/benefit package commensurate with experience. Contact: Ruth Koch, (800) 368-2416, Extension 104.

SEATTLE — Expanding, 68-physician, multispecialty group seeking sixth BE/BC neurologist-subspecialty training preferred. Options for academic affiliation. Epilepsy, stroke, geriatrics, electrophysiology and movement disorder are areas of need. Send CV to: The Polyclinic, Attention: Robert Schroeder, Administrator, 1145 Broadway, Seattle, WA 98122-4299.

THE DEPARTMENT OF NEUROLOGY at Henry Ford Health Sciences Center is looking for BC/BE clinical neurologists with expertise in electromyography and electroencephalography to join a very active clinical neurophysiology section where over 10,000 studies are performed annually. Qualified individuals are expected to teach Neurology residents (inpatient and outpatient), participate in training of residents and fellows in clinical neurophysiology, and work cooperatively in a 20-neurologist department. Research opportunities and facilities exist in a number of related areas including MEG. Contact: K.M.A. Welch, MD, William T. Cossett Chair, Department of Neurology, Henry Ford Hospital, 2799 West Grand Boulevard, Detroit, MI 48202.

NEUROLOGIST — The Cleveland VA Medical Center is recruiting for a part-time (5/8) position for a neurologist. The applicant must be board-certified or board-eligible in neurology, have expertise in both EMG and EEG and satisfy requirements for appointment in the Neurology Department at Case Western Reserve University. Responsibilities include attending neurology outpatient clinics in Youngstown, Canton, Brecksville, and Cleveland, Ohio, in addition to his/her responsibility for inpatient, consult services, reading EEGs and performing EMGs. Interested individuals should contact: Thomas R. Claflin at (216) 526-3030, Extension 7916. Or send a resume to his attention: Personnel Service 05(B), VAMC, 10000 Brecksville Road, Brecksville, OH 44141. The Cleveland VAMC is proud to be an equal employment opportunity employer.

PLEASE NOTE—Address replies to box number ads as follows: Box number ______, c/o AON, P.O. Box 1510, Clearwater, FL 34617.

Professional Opportunities

METROPOLITAN NEW YORK CITY — BC/B neurologist to join solo general practice. EMG EP/EEG experience preferred. Excellent financia package. University affiliation. Send CV to: Alla Perel, MD, 1055 Hylan Boulevard, Staten Island, N 10305.

Positions Available

NEW ENGLAND SEACOAST COMMUNITY seek second neurologist for community hospital prac- tice. Excellent location with abundant outdoo recreation, good schools, major scientific institu tions nearby. First year salary with early partnersh option. Please contact: Michael Leahy, MD, Bramblebush Park, Falmouth, MA 02540.

NEUROLOGIST: BC/BE. Must have skills in EEG, EMG and evoked potentials. To be associated wit two neurologists in private practice, in a medica center location, with a expanding modern 181-bed hospital with complete modern equipment, and all specialties are represented. Situated in an attractive high desert area of the northwest with abundan recreational activities including the finest skiing, hiking, hunting, and fishing. Excellent schools available, both public and private. This is a very active practice in a drawing area of 175,000 and an excellent opportunity. Reply with curriculum vitae to: Bo #823, c/o AON.

Faculty Positions

BE/BC NEUROLOGIST, subspecialty expertis neuro-oncology, including chemotherapy, resear and teaching. Assistant Professor with tenure earning option. Salary and benefits negotiable. November 1, 1991 start. Contact: Leon D. Prockop, MD, Chairman Neurology Department, (813) 974-2794. University of South Florida is an affirmative action/equal opportunity employer.

Faculty Positions

ACADEMIC NEUROLOGIST sought with fellowship training in neuromuscular diseases and EMG. Opportunity to develop research program, teach neurology residents, and start a fellowship. State-of-the-art equipment and technician furnished. Nerve and muscle biopsy laboratory available in the department. Reply with CV to: Joseph B. Green, MD, Chairman, Department of Medical and Surgical Neurology, Texas Tech University Health Sciences Center, Lubbock, TX 79430. Texas Tech University is an equal opportunity employer.

ACADEMIC NEUROLOGIST sought with competence in sleep disorders to direct sleep center. Opportunity also in epilepsy, EEG, and evoked potentials, teach neurology residents and students. Reply with CV to: Joseph B. Green, MD, Chairman, Department of Medical and Surgical Neurology, Texas Tech University Health Sciences Center, Lubbock, TX 79430. Texas Tech University is an equal opportunity employer.

ACADEMIC NEUROLOGIST sought with training in cerebrovascular disease to develop program. Collaborate with neuropathology and radiology to develop research. Teach neurology residents. Reply with CV to: Joseph B. Green, MD, Chairman, Department of Medical and Surgical Neurology, Texas Tech University Health Sciences Center, Lubbock, TX 79430. Texas Tech University is an equal opportunity employer.

ACADEMIC NEUROLOGIST: A full-time academic position is available at the Assistant Professor level at Vanderbilt University Medical Center. Candidates should be board-certified/board-eligible in neurology and should have completed two years of full-time fellowship in epilepsy and clinical neurophysiology. The position includes teaching responsibilities and research. The preferred candidate will have experience in clinical epilepsy, long-term monitoring, electrocorticography, and experimental drug studies. Interested individuals should send CV to: Bassel Abou-Khalil, MD, Department of Neurology, Vanderbilt University Medical Center, 2100 Pierce Avenue, Room 336, Nashville, TN 37212.

Faculty Positions

THE DEPARTMENT OF NEUROLOGY at The University of Iowa is recruiting a full-time faculty member (Assistant Professor level) to join two other members in the Division of Cerebrovascular Diseases. The Division of Cerebrovascular Diseases has an active program in education, patient care, and research, and is leading a large multi-center clinical trial in acute stroke therapy. Appointees are expected to join in the Division's activities and to conduct an independent program of scientific investigation. The new faculty member should be qualified to practice medicine in Iowa, board-certified or -eligible in neurology, and have had additional training, preferably through a fellowship, in cerebrovascular disease. Please send inquiries to: Antonio R. Damasio, MD, Professor and Head, Department of Neurology, University of Iowa, Iowa City, IA 52242. The University of Iowa is an equal opportunity, affirmative action employer. Women and minorities are encouraged to apply.

THE SCHOOL OF MEDICINE of the University of Missouri Health Sciences Center is seeking applications and nominations for the position of Professor and Chairperson of the Department of Neurology. The candidate must have senior academic experience with commitment to education and research. Demonstrated leadership and administrative capabilities are essential. The Chair is responsible for recruitment and retention of faculty, education of medical students and residents, the development of research programs and the Neurology clinical services in the University Hospital and Clinics. Send applications to: Donald H. York, PhD, Chair, Neurology Search Committee, University of Missouri-Columbia, School of Medicine, Office of the Dean, Columbia, MO 65212. The University of Missouri-Columbia is an equal opportunity and affirmative action institution. Females and minorities are encouraged to apply.

PLEASE NOTE—Address replies to box number ads as follows: Box number ______, c/o AON, P.O. Box 1510, Clearwater, FL 34617.

ADULT NEUROLOGIST

Immediate private practice, solo and group opportunities available for board certified or board admissible neurologist in the following locations:

NASHVILLE, TENNESSEE   *NORTH CENTRAL INDIANA
****NORTH WEST LOUISIANA   *SOUTH EAST TEXAS***
****FLORIDA GULF COAST***

You will find excellent private practice opportunities in family oriented communities, competitive practice establishment packages which include salary/revenue guarantee, relocation and much more. Residencies

NEUROLOGY RESIDENCY PROGRAM at the University of North Carolina. PGYII position available for entrance into Neurology Residency Program for 1992. Appointment will be made through the Neurology Residency Matching Program in 1992. Our program offers strong clinical training in general adult and child neurology as well as subspeciality exposure to epilepsy, sleep disorders, neuromuscular diseases and pain. For information contact: John A. Messenheimer, MD, School of Medicine, Department of Neurology, University of North Carolina, CB #7025, 751 Clinical Sciences Building, Chapel Hill, NC 27599-7025. (919) 966-3707.

THE UNIVERSITY OF Cincinnati Neurology Department is offering a second year neurology residency position (PGY III) beginning as soon as possible. For information contact: Joseph P. Broderick, MD, Residency Director, Department of Neurology, University of Cincinnati Medical Center, Cincinnati, OH 45267-0525. (513) 558-5431.

Fellowships

FELLOWSHIP IN CEREBROVASCULAR disease: Fellowships in cerebrovascular disease are available in the Department of Neurology at the University of Iowa. Comprehensive clinical training in diagnosis and management of patients with stroke is complemented by opportunities for clinical or basic research. Fellows are active participants in patient care and collaborate in several on-going local and multi-center clinical research studies. Candidates should be board-eligible or -certified in neurology and licensed to practice medicine in the United States. Please send inquiries to: Harold P. Adams, Jr, MD, Division of Cerebrovascular Diseases, Department of Neurology, University of Iowa, Iowa City, IA 52242; or call: (319) 356-4110. The University of Iowa is an affirmative action, equal opportunity employer. Women, minorities, and handicapped are encouraged to apply.

NATIONAL STROKE ASSOCIATION announces career-development fellowship awards ($30,000/year) for stroke research. Application due January 15, 1992 for July 1992 commencement. Contact: National Stroke Association, 300 East Hampden Avenue, #240, Englewood, CO 80110. (303) 762-9922.

PAIN FELLOWSHIP — The Pain Service in the Department of Neurology at Memorial Sloan-Kettering Cancer Center is seeking a board-eligible/board-certified neurologist for a pain fellowship. This is a one or two year position which offers comprehensive training in pain evaluation and treatment with a strong emphasis on cancer pain. Fellows will participate in clinical investigations of neuro-oncologic pain syndromes and the pharmacology of opioid analgesics. Laboratory research opportunities directed at the mechanisms of opiate action and the molecular pharmacology of opiate receptors are also available. Please contact: Kathleen M. Foley, MD, Department of Neurology, Memorial Sloan-Kettering Cancer Center, 1275 York Avenue, New York, NY 10021.

NEURO-ONCOLOGY Fellowships/Instructorships: July 1992 and 1993 — Neuro-oncology fellowships/instructorships are available for July 1992 and 1993. The University of California, San Francisco, Department of Neurological Surgery, Neuro-Oncology Service, offers unprecedented opportunities to participate in chemotherapy and radiation therapy trials of children and adults with brain tumors. Practice is primarily outpatient with some 2,000 patient visits each year. A fully funded second year of laboratory research is available. Applicants for this position must be eligible for a California medical license and be board-eligible or board-certified in neurology, neurosurgery, or medical oncology. There are two positions available. Apply to: Michael Prados, MD, Department of Neurological Surgery, M-787, Neuro-Oncology Service, University of California, San Francisco, 505 Parnassus Avenue, San Francisco, CA 94143-0112. The University of California is an equal opportunity/affirmative action employer. Women and minorities are encouraged to apply.

Fellowships

Neurobehavior Fellowship

Emory University School of Medicine invites applications for a one- or two-year fellowship in behavioral neurology, beginning on or after July 1, 1992. The fellowship will offer exposure to the neurology and neuropsychology of dementia, stroke, head injury, temporal lobe epilepsy, movement disorders, and atypical psychiatric disorders.

The fellow will be encouraged to intensively participate in one of the research activities of the program. Current clinical research includes drug trials for Alzheimer's disease, cognitive evoked potentials in aging and stroke, and the behavioral problems associated with temporal lobe epilepsy. Current basic research involves cellular neuroanatomy and neurophysiology relating to neuronal injury.

Please send letter of inquiry and CV to:

Robert C. Green, MD

Telephone: (404) 728-6682

An equal opportunity employer.

NEUROEPIDEMIOLOGY: Training fellowship available for board-eligible neurologist beginning July 1, 1992, at the Sergievsky Center and Neurological Institute, Columbia-Presbyterian Medical Center. Opportunity to earn a MS or MPH in epidemiology at the School of Public Health and work on ongoing clinical studies. Special interest in cerebrovascular disease or epilepsy preferred. Address inquiries to: Dr. Ralph L. Sacco, Neurological Institute, 710 West 168th Street, New York, NY 10032. Columbia University is an equal opportunity employer.

FELLOWSHIP IN NEUROLOGY OF AGING — A fellowship is available for July, 1992, for the Neurobiology of Aging. The position includes opportunities for both clinical and basic research, as well as experience in the diagnosis and management of neurologic disorders occurring with age. The fellowship is for one or two years, and will include opportunities for participation in ongoing studies in neuropharmacology, neuropathology, molecular neurobiology, neuropsychology and the deisgn of clinical studies. Neurology residency training or equivalent experience is required. The fellowship is in the Neurology Department at the University of Massachusetts Medical Center. Reply to: David A. Drachman, MD, Professor and Chairman, Department of Neurology, University of Massachusetts Medical Center, 55 Lake Avenue North, Worcester, MA 01655 USA. EOE.

We Target The Physician You Want!

The *Archives of Neurology's* classified recruitment advertising section is seen by precisely the physician you need – neurologists, child neurologists and neurological surgeons. A specialized physician audience of over 16,000.

Send us your advertising order today. Just complete the coupon below and attach your typewritten copy. The next available issue is December which closes Friday, October 25th.

The classified rate is $1.00 per word for one issue. For three issues or more, the rate is $.90 per word per issue. Minimum classified ad is 20 words.

Dilantin® Kapseals®

(extended phenytoin sodium capsules, USP)

Dilantin® KAPSEALS® (Extended Phenytoin Sodium Capsules, USP)

Before prescribing, please see full prescribing information. A Brief Summary follows.

INDICATIONS AND USAGE: Dilantin is indicated for the control of generalized tonic-clonic (grand mal) and complex partial (psychomotor, temporal lobe) seizures and prevention and treatment of seizures occurring during or following neurosurgery.

Phenytoin serum level determinations may be necessary for optimal dosage adjustments (see Dosage and Administration and Clinical Pharmacology in the full prescribing information).

CONTRAINDICATIONS: Phenytoin is contraindicated in those patients who are hypersensitive to phenytoin or other hydantoins.

WARNINGS: Abrupt withdrawal of phenytoin in epileptic patients may precipitate status epilepticus. When, in the judgment of the clinician, the need for dosage reduction, discontinuation, or substitution of alternative antiepileptic medication arises, this should be done gradually. However, in the event of an allergic or hypersensitivity reaction, rapid substitution of alternative therapy may be necessary. In this case, alternative therapy should be an antiepileptic drug not belonging to the hydantoin chemical class.

There have been a number of reports suggesting a relationship between phenytoin and the development of lymphadenopathy (local or generalized) including benign lymph node hyperplasia, pseudolymphoma, lymphoma, and Hodgkin's Disease. Although a cause and effect relationship has not been established, the occurrence of lymphadenopathy indicates the need to differentiate such a condition from other types of lymph node pathology. Lymph node involvement may occur with or without symptoms and signs resembling serum sickness, eg, fever, rash and liver involvement.

In all cases of lymphadenopathy, follow-up observation for an extended period is indicated and every effort should be made to achieve seizure control using alternative antiepileptic drugs.

Acute alcoholic intake may increase phenytoin serum levels while chronic alcoholic use may decrease serum levels.

In view of isolated reports associating phenytoin with exacerbation of porphyria, caution should be exercised in using this medication in patients suffering from this disease.

Usage in Pregnancy: A number of reports suggests an association between the use of antiepileptic drugs by women with epilepsy and a higher incidence of birth defects in children born to these women. Data are more extensive with respect to phenytoin and phenobarbital, but these are also the most commonly prescribed antiepileptic drugs; less systematic or anecdotal reports suggest a possible similar association with the use of all known antiepileptic drugs.

The reports suggesting a higher incidence of birth defects in children of drug-treated epileptic women cannot be regarded as adequate to prove a definite cause and effect relationship. There are intrinsic methodological problems in obtaining adequate data on drug teratogenicity in humans; genetic factors or the epileptic condition itself may be more important than drug therapy in leading to birth defects. The great majority of mothers on antiepileptic medication deliver normal infants. It is important to note that antiepileptic drugs should not be discontinued in patients in whom the drug is administered to prevent major seizures, because of the strong possibility of precipitating status epilepticus with attendant hypoxia and threat to life. In individual cases where the severity and frequency of the seizure disorder are such that the removal of medication does not pose a serious threat to the patient, discontinuation of the drug may be considered prior to and during pregnancy, although it cannot be said with any confidence that even minor seizures do not pose some hazard to the developing embryo or fetus. The prescribing physician will wish to weigh these considerations in treating or counseling epileptic women of childbearing potential.

In addition to the reports of increased incidence of congenital malformation, such as cleft lip/palate and heart malformations, in children of women receiving phenytoin and other antiepileptic drugs, there have more recently been reports of a fetal hydantoin syndrome. This consists of prenatal growth deficiency, microcephaly and mental deficiency in children born to mothers who have received phenytoin, barbiturates, alcohol, or trimethadione. However, these features are all interrelated and are frequently associated with intrauterine growth retardation from other causes.

There have been isolated reports of malignancies, including neuroblastoma, in children whose mothers received phenytoin during pregnancy.

An increase in seizure frequency during pregnancy occurs in a high proportion of patients, because of altered phenytoin absorption or metabolism. Periodic measurement of serum phenytoin levels is particularly valuable in the management of a pregnant epileptic patient as a guide to an appropriate adjustment of dosage. However, postpartum restoration of the original dosage will probably be indicated.

Neonatal coagulation defects have been reported within the first 24 hours in babies born to epileptic mothers receiving phenobarbital and/or phenytoin. Vitamin K has been shown to prevent or correct this defect and has been recommended to be given to the mother before delivery and to the neonate after birth.

PRECAUTIONS: General: The liver is the chief site of biotransformation of phenytoin; patients with impaired liver function, elderly patients, or those who are gravely ill may show early signs of toxicity.

A small percentage of individuals who have been treated with phenytoin has been shown to metabolize the drug slowly. Slow metabolism may be due to limited enzyme availability and lack of induction; it appears to be genetically determined.

Phenytoin should be discontinued if a skin rash appears (see "Warnings" section regarding drug discontinuation). If the rash is exfoliative, purpuric, or bullous or if lupus erythematosus, Stevens-Johnson syndrome, or toxic epidermal necrolysis is suspected, use of this drug should not be resumed and alternative therapy should be considered. (See Adverse Reactions.) If the rash is of a milder type (measles-like or scarlatiniform), therapy may be resumed after the rash has completely disappeared. If the rash recurs upon reinstitution of therapy, further phenytoin medication is contraindicated.

Phenytoin and other hydantoins are contraindicated in patients who have experienced phenytoin hypersensitivity. Additionally, caution should be exercised if using structurally similar (eg, barbiturates, succinimides, oxazolidinediones and other related compounds) in these same patients.

Hyperglycemia, resulting from the drug's inhibitory effects on insulin release, has been eported. Phenytoin may also raise the serum glucose level in diabetic patients.

Osteomalacia has been associated with phenytoin therapy and is considered to be due to henytoin's interference with Vitamin D metabolism.

Phenytoin is not indicated for seizures due to hypoglycemic or other metabolic causes. ppropriate diagnostic procedures should be performed as indicated.

Phenytoin is not effective for absence (petit mal) seizures. If tonic-clonic (grand mal) and bsence (petit mal) seizures are present, combined drug therapy is needed.

Serum levels of phenytoin sustained above the optimal range may produce confusional states referred to as "delirium," "psychosis," or "encephalopathy," or rarely irreversib
dysfunction. Accordingly, at the first sign of acute toxicity, plasma levels are recomm
reduction of phenytoin therapy is indicated if plasma levels are excessive; if symp
termination is recommended. (See Warnings.)

Information for Patients: Patients taking phenytoin should be advised of the ir
adhering strictly to the prescribed dosage regimen, and of informing the physician
condition in which it is not possible to take the drug orally as prescribed, eg, sur

Patients should also be cautioned on the use of other drugs or alcoholic beverage
seeking the physician's advice.

Patients should be instructed to call their physician if skin rash develops.

The importance of good dental hygiene should be stressed in order to r
development of gingival hyperplasia and its complications.

Do not use capsules which are discolored.

Laboratory Tests: Phenytoin serum level determinations may be necessary to ach
dosage adjustments.

Drug Interactions: There are many drugs which may increase or decrease pheny
which phenytoin may affect. Serum level determinations for phenytoin are espe
when possible drug interactions are suspected. The most commonly occurring drug
are listed below: 1. Drugs which may increase phenytoin serum levels include: a
intake, amiodarone, chloramphenicol, chlordiazepoxide, diazepam, dicumarol,
estrogens, H_2-antagonists, halothane, isoniazid, methylphenidate, phen
phenylbutazone, salicylates, succinimides, sulfonamides, tolbutamide, trazodon

2. Drugs which may decrease phenytoin levels include: carbamazepine, chronic al
reserpine, and sucralfate. Moban® brand of molindone hydrochloride contains c
which interfere with the absorption of phenytoin. Ingestion times of phenytoin
preparations containing calcium should be staggered in patients with low serum phe
to prevent absorption problems.

3. Drugs which may either increase or decrease phenytoin serum levels include: ph
sodium valproate, and valproic acid. Similarly, the effect of phenytoin on phenobarb
acid and sodium valproate serum levels is unpredictable.

4. Although not a true drug interaction, tricyclic antidepressants may precipitat
susceptible patients and phenytoin dosage may need to be adjusted.

5. Drugs whose efficacy is impaired b
include: corticosteroids, coumarin anti
digitoxin, doxycycline, estrogens, furos
contraceptives, quinidine, rifampin, th
vitamin D.

Drug/Laboratory Test Interactions: Phe
cause decreased serum levels of protein-b
(PBI). It may also produce lower than norm
dexamethasone or metyrapone tests. Phe
cause increased serum levels of glucose, al
phatase, and gamma glutamyl transpeptic

Carcinogenesis: See "Warnings" section f
tion on carcinogenesis.

Pregnancy: See Warnings.

Nursing Mothers: Infant breast-feeding is not recommended for women taking this dr
phenytoin appears to be secreted in low concentrations in human milk.

ADVERSE REACTIONS: Central Nervous System: The most common manifestations e
with phenytoin therapy are referable to this system and are usually dose-related. Th
nystagmus, ataxia, slurred speech, decreased coordination and mental confusion.
insomnia, transient nervousness, motor twitchings, and headaches have also been obse
have also been rare reports of phenytoin induced dyskinesias, including chorea, dysto
and asterixis, similar to those induced by phenothiazine and other neuroleptic drugs.

A predominantly sensory peripheral polyneuropathy has been observed in patient
long-term phenytoin therapy.

Gastrointestinal System: Nausea, vomiting, constipation, toxic hepatitis and liver

Integumentary System: Dermatological manifestations sometimes accompanied b
included scarlatiniform or morbilliform rashes. A morbilliform rash (measles-like) i
common; other types of dermatitis are seen more rarely. Other more serious forms
be fatal have included bullous, exfoliative or purpuric dermatitis, lupus erythematosu
Johnson syndrome, and toxic epidermal necrolysis (see Precautions).

Hemopoietic System: Hemopoietic complications, some fatal, have occasionally bee
in association with administration of phenytoin. These have included thrombocytope
penia, granulocytopenia, agranulocytosis, and pancytopenia with or without bone m
pression. While macrocytosis and megaloblastic anemia have occurred, these conditio
respond to folic acid therapy. Lymphadenopathy including benign lymph node hyperpl
dolymphoma, lymphoma, and Hodgkin's Disease have been reported (see Warning

Connective Tissue System: Coarsening of the facial features, enlargement of the lip
hyperplasia, hypertrichosis and Peyronie's Disease.

Cardiovascular: Periarteritis nodosa.

Immunologic: Hypersensitivity syndrome (which may include, but is not limited to,
such as arthralgias, eosinophilia, fever, liver dysfunction, lymphadenopathy or rash)
lupus erythematosus, immunoglobulin abnormalities.

OVERDOSAGE: The lethal dose in children is not known. The lethal dose in adults is
to be 2 to 5 grams. The initial symptoms are nystagmus, ataxia, and dysarthria. Othe
tremor, hyperreflexia, lethargy, slurred speech, nausea, vomiting. The patient ma
comatose and hypotensive. Death is due to respiratory and circulatory depression.

There are marked variations among individuals with respect to phenytoin plasma le
toxicity may occur. Nystagmus, on lateral gaze, usually appears at 20 mcg/mL, at
mcg/mL, dysarthria and lethargy appear when the plasma concentration is over 40 mc
as high a concentration as 50 mcg/mL has been reported without evidence of toxicity
as 25 times the therapeutic dose has been taken to result in a serum concentratio
mcg/mL with complete recovery.

Treatment: Treatment is nonspecific since there is no known antidote.

The adequacy of the respiratory and circulatory systems should be carefully obs
appropriate supportive measures employed. Hemodialysis can be considered since
is not completely bound to plasma proteins. Total exchange transfusion has been u
treatment of severe intoxication in children.

In acute overdosage the possibility of other CNS depressants, including alcohol,
borne in mind.

Caution – Federal law prohibits dispensing without prescription. 0

As rare as a seizure on Dilantin® (extended phenytoin sodium capsules, USP) 100 mg

For as many as 86% of patients, seizures occur only once in a blue moon—if at all—once Dilantin monotherapy is under way.[1]

That fact holds true for partial, complex partial, generalized tonic-clonic seizures, and status epilepticus.

And it's achieved *without* significant cognitive impairment at therapeutic drug levels (10 to 20 μg/mL),[2] often *with* once-daily therapy (Dilantin® Kapseals®), which enhances compliance.

What you demand, Dilantin does—for millions of patients every day.

That's why Dilantin remains a drug of choice.

And that's why most patients on Dilantin will wait a long, long time to see another seizure.

Dilantin®

Once in a blue moon" describes the phenomenon in which the moon appears as a brilliant blue. Seen worldwide following the volcanic eruption of Krakatoa in 1883, the blue moon occurs only when atmospheric cloud droplets, each less than 5 μm in diameter, form in abundance—an exceedingly rare event.[3]
